INDEX TO VOLUME I FOR 1943

READERS in search of a particular subject will find it useful to bear in mind that the references are in several cases distributed under two or more separate headings—for example, Brain and Cerebral ; Heart and Cardiac ; Liver and Hepatic ; Renal and Kidney ; Cancer and Carcinoma ; Child and Infant ; Goitre and Thyroid. Subjects dealt with under various main headings in the JOURNAL have been set out in alphabetical order under their respective headings—for example, " Annotations," " Correspondence," " Leading Articles," " Obituary," " Reviews," etc. Original Articles are indicated by the letter (O).

A

ABBOTT, W. N : Pulmonary disease in miners, 581
—— W. O : *Decompression of the Intestinal Tract*, 73
Abdomen : Abdominal wounds in war : treatment of individual lesions (Sir James Walton), 61 (O)
—— severe gunshot wound of (W. P. Griffin), 352
—— blast injury to, by depth charge (D. D. Pinnock and P Wood), 537 (O) ; correspondence, 648
—— regional analgesia for operations on (book review), 666
Abel, Rudolf, death of, 367
Abortion, habitual, 807
Abortus fever (D. G Leys), 187 (O) ; correspondence, 299, 394, 425, 677—Bovine brucellosis (leading article), 387
RAHAMS, Sir Adolphe : Vitamins and physical efficiency, 394, 580—The M'Naghten rules, 707
Absence, sick, among munition workers, 110
Absenteeism in industry, 303, 429
T, Isaac A. and Arthur F : *The 1942 Year Book of Pediatrics*, 789
Abyssinia : Memorial hospital to Princess Tsahai, 37—Medical services for, 239

ACADEMY, ROYAL, OF MEDICINE IN IRELAND :
  Section of Medicine : Giardia lamblia infestation, report on, 456—Miliary tuberculosis, 517
  Section of Obstetrics. Pseudo-hermaphroditism, 486—Action of drugs on the uterus, 643
  Section of Pathology : Adrenal neuroblastoma, 51
  Section of Anatomy and Physiology : Functions of the pyloric canal, 142
  Section of Obstetrics : Placental polypus, 229

Accident service, future civil : report on, to British Orthopaedic Association, 484
Accidents, analysis of statistics, 29
—— industrial, statistics, 744
—— need for national policy, 360
Acetarsol vaginal compound, 478
Acid, alkali, and meals, effect of, on blood level and excretion of sulphapyridine in children (H. Ellis C Wilson), 507 (O)
—— phosphatase and prostatic cancer (leading article), 571
Adam, Thomas Blane, obituary notice of, 431
Adams, Alfred, obituary notice of, 237
—— D. : Jamaica Medical Service, 148
Adder bite, 55, 769
Addison's disease, desoxycorticosterone in : a comparison of different methods of administration (D M Dunlop), 557 (O)
Adenocarcinoma *See* Cancer
Adoption of children, 115, 235

ADRENALS :
  Adrenal cortical therapy, 433
  —— neuroblastoma, 51
  —— pituitary disorders (S. L. Simpson), 247
  Adrenalectomy and loss of hair in rats (L. Stein and E. Wertheimer), 217
  Desoxycorticosterone acetate and natural extracts of suprarenal cortex, 701
  Fulminating purpura and adrenal haemorrhage, 22, 120
  Haemorrhagic suprarenal infarction, 22

Africa, visits to, by medical advisers to Colonial Office, 79
Agglutination reactions, abnormal, of a strain of *Leptospira icterohaemorrhagiae* (J. C Broom and H. C. Brown), 783 (O)
Agriculture : Cottages for farm workers, 240
Aiton, Temp. Surg Lieut. Archibald Barr, " missing, believed killed," 117
Akwei, Eustace, disclaimer by, 622
ALBERT, S. (and Hans SELYE) : Gonad-protecting power of steroids, 679
COCK, Helen Bower : Future of women in medicine, 393
ocke, Nicholas, surgeon to Henry VIII and Edward VI, 20
Alcohol, venereal disease and, 528
XANDER, Harry L. : *Synopsis of Allergy*, 353
Alimentary tract dysfunction, psychological factors in, 516
Alimentation, intravenous (leading article), 416
Alkali, acid, and meals, effect of, on blood level and excretion of sulphapyridine in children (H. Ellis C Wilson), 507 (O)
Alkaptonuria, diagnosis of (J. Noël Gould and Tudur Glyn Thomas), 788
ALLAN, Malcolm : Contaminated injection, 776
Allen, Edgar, death of, 650
—— Frank James, obituary notice of, 86 ; corrigendum, 148
—— Frederick M : Calorie control diabetic diet, 676
—— F. R. W K . Hand and finger lesions, 654
Allergy : Social aspects of (E. M Fraenkel), 216 (O)—Synopsis of (book review), 353—To liver extract, 370, 528, 613—Irritant spectacle frames, 493, 552, 648
—— nasal (R.S.M.), 674
ALLOTT, E. N : Blood serum in Raynaud's disease, 455
AMBERSON, J. Burns (and others) : *Modern Aspects of the Anti-tuberculosis Program*, 255
America : Association for the Advancement of Psychoanalysis, New York, 208—Tuberculosis studies from (book review), 255—American Library in London, 651
—— South, cancer research in, 14
Amino-acridine compounds. *See* Flavines
Amnioplastin as absorbable tissue isolator (Lambert Rogers), 423
AMOR, Arthur J. : *X-ray Atlas of Silicosis*, 2nd ed , 192—The nature of industrial medicine, 514
Amphetamine sulphas, use of, in facilitating electrically induced convulsions (K. C. Bailey), 250 (O)
Amputation stumps, cineplastic, review of book on, 696
Anaemia : Iron for, 242—Is is prevalent? (leading article), 449 , correspondence, 612—Hypopituitarism, hypogonadism, 776
—— haemolytic, of the newborn, Rh factor in (T. W Lloyd), 132
—— macrocytic, of pregnancy and puerperium (H. W Fullerton), 158 (O)—Following partial gastrectomy (A. J. Rhodes and A. Grunberg), 726
—— pernicious : Of pregnancy (leading article), 105 ; correspondence, 233—Intolerance to liver extract in (E. Delikat), 539 (O) ; correspondence, 613—Treated with pyloro-duodenal extract and liver in tablet form (binaemon) (J. Stewart Lawrence), 567—Treatment with an experimental proteolysed liver preparation ; preliminary observations (L. J. Davis and others), 655 (O)
Anaesthesia : For laryngofissure (C. W. Lewis), 162 ; correspondence, 230, 302, 334, 395, 458—Case of anaphylaxis after (novutox), (R Armattoe), 191—Oxford ether vaporizer, 232, 556—With special reference to dentistry (book review), 353—Brain volume during (annotation), 357—Recent advances (book review), 415—And analgesia in obstetrical practice (R S.M), 577
—— endotracheal, review of book on, 478
—— peroral intratracheal, universal apparatus for (G Hornby and M. Hawksley), 317 (O)
—— refrigeration (leading article), 573
—— regional (annotation), 700
—— trichlorethylene, 398—In plastic surgery (R A. Gordon and R. P W. Shackleton), 380 (O)—A note on (J. Haworth and A. Duff), 381 (O) ; correspondence, 489, 582
Anaesthetic deaths, epiglottis in, 590
Anaesthetics afloat, review of book on, 221
Analgesia, ethyl chloride (J. D. Rochford and B. T. Broadbent), 664
—— regional, for abdominal operations (book review), 666
Anaphylaxis after novutox anaesthesia (R. Armattoe), 191
Anatomical nomenclature, 492
Anatomy of central nervous system, review of book on, 478
—— principles of, and the peripheral nerves (Section of Physical Medicine, R.S.M.), 197
ANDERSON, A. B. : Lactation tetany, 517
—— A. F : Scientific freedom and social medicine, 393
—— B. G. (and J. F. SADUSK) : Chancre of the gum, 56
—— C Woodroffe (and W. Powell PHILLIPS) : *Preventive Inoculation*, 353
ANDERSON, Thomas. Chemotherapy in pneumonia, 485—Some aspects of the chemotherapy of pneumonia, 717 (O)
—— W. L. (and D. B. BRADSHAW) : A case of malignant tertian malaria, 508 ; correspondence, 613, 622, 678, 714
ANDRATSCHKE, B. (and C. H. ROGERSON) : Mild depressive psychosis, 780
ANDREWES, C. H : Influenza vaccination, periodicity, and virus, 643
Androstenediol, action of, with testosterone (Hans Selye and S. Albert), 679
Aneurysm of the hepatic artery, a note on, with reference to a rare cause of severe gastro-intestinal haemorrhage (G Gordon-Taylor), 504 (O)

Annotations :
  Anaesthesia, brain volume during, 357
  —— refrigeration, 573
  —— regional, 700
  Anti-social behaviour disorders, 195
  Any Questions? 226
  Appendicitis, appendical mechanics and, 511
  Arthritis, rheumatoid, peripheral nerves in, 640
  Asthma, theophylline for, 731
  Blindness, causes of, 387
  Blood groups, determination of, 764
  Boyd, Dr. Robert : Gift to Manchester, 138
  Brain, hypoglycaemia and the, 672
  Bronchiectasis and collapse, 77
  Brucellosis, bovine, 387
  Buzzard, Sir Farquhar, 226
  Cancer, oesophageal, surgery of, 48
  —— prostatic, castration for, 545
  Children : Four-year plan for nurseries, 639
  Collapse and bronchiectasis, 77
  Contracture, ischaemic, treatment of, 108
  Czechoslovak medical degrees conferred at Oxford, 325
  Desoxycorticosterone and fluid metabolism, 513
  —— and natural extracts of suprarenal cortex, 701
  Diabetes : Oestrogen treatment of, 107—Treatment of diabetic coma, 166—Retinal venous changes in, 546
  Diet, influence of, on renal volume, 226
  —— and trinitrotoluene poisoning, 671
  Drugs of addiction, control of, 512
  Epidemiology of streptococcal infections, 195
  Europe, starvation in, 46
  Feeding, communal, standardization in, 293
  Food yeast, 294
  France, Southern, starvation in, 166
  Front line, a county borough in the (review of *War over West Ham*), 764
  Harben gold medal, 482
  Health Education Journal, 388
  —— —— for girls, 672
  —— and hygiene, industrial, 356
  —— units for West Indies, 639
  Hospital, British, for Stalingrad, 701
  Housing, an inquiry, 700
  Hydrocephalus, communicating, surgery of, 357
  Hygiene, tropical, 638
  Indexes, half-yearly, 260
  Infantile mortality, causes of, 19
  Influenza prevention, 17
  Injection, the contaminated, 608
  Jaundice and yellow fever vaccine, 77
  —— inquiry into growing incidence of, 609
  Keratoconjunctivitis, epidemic, 418
  Ketosis and gonadotrophin secretion, 419
  Liver function, hippuric acid synthesis and, 546
  —— puncture, 78
  —— side-tracking the, 482
  Lung-dusting experiments, 18
  Lungs : Pulmonary congestion and oedema, 451
  Lymphopathia venereum, 17
  Medical folklore, 452
  —— journalism. 75th birthday of the *Practitioner*, 731
  —— practitioner as teacher, 701
  —— training, breadth or depth in? 640
  Medicine, industrial, research in, 672
  Milk, compulsory pasteurization, 512
  Mosquitoes, control of, in Britain, 482
  Mouth, occupation and the, 356
  Nerve injuries, peripheral, aids to the investigation of (M.R.C. War Memorandum), 78

Annotations (*continued*):
Nerve injuries, peripheral, diagnosis of, 138
Neutrons, slower, 481
Newborn, care of the, 259
Orchitis of mumps, operation for, 138
Pasteurization, doctors agree about, 258
Pathological laboratories, supplies for, 18
Penicillin, 481
Periarteritis nodosa, new light on, 608
Phenobarbital, skin reaction to, 763
Plague abroad, 699
Pleuritis, aseptic obliterative, silver nitrate for, 419
Pneumonia, primary atypical, aetiology unknown, 225
Poliomyelitis virus in water, 545
Polyneuritis, infectious; 292
Pregnancy, tetany in, treatment of, 418
Progesterone and vitamin E, 259
Propamidine, 324
Protein reservoir, 572
Quinine substitutes, 452
Riboflavin and corneal vascularization, 545
Russia, surgical mission to, 701
Scabies on the screen, 451
Shipwrecked, help for the, 167
Silicosis in Sweden, 260
Sprue syndrome, pathogeny of, 639
Starvation in Europe, 46
—— in Southern France, 166
Surgery of tendons, 325
Tract for the times (hours of work), 609
Tuberculin and radiological survey, combined, 47
Tuberculosis, endobronchial, 294
—— experimental, 196
—— incubation period in, 260
—— pulmonary, diet in, 574
Tuberculous cavities, treatment of, 763
Ulcer, duodenal, physiological gastrectomy for, 388
—— peptic, pathogenesis of, 165
—— —— of the oesophagus, 573
Vaccination, B C G, 167
Vaccine, yellow fever, and jaundice, 77
Venereal disease, cerebral reactions to anti-syphilitic therapy, 671
—— —— statistics of, 137
—— —— in Sweden, 574
Vitamin C and carbohydrate metabolism, 608
—— E, progesterone and, 259
Vitamins and physical fitness, 417
Wasting disease and lesions of the nervous system, 195
Wilson, Sir Charles, the Prime Minister's physician, 78
Woman, the heaviest, 108
Wounds, antiseptic treatment of, 106
Youth registration and hours of work, 730

Anoxia, crush injury and, 708
Anstey-Chave, Thomas, obituary notice of, 399
Antaki, Capt. Albert Joseph, death of, 117
Antiseptics, surface: present status of amino-acridine compounds (flavines) (C. H. Browning), 341 (O); leading article on, 355; correspondence, 486
Anti-social behaviour disorders (annotation), 195
Aorta, pregnancy and labour in a case of congenital coarctation of the (C. M. Walker), 90 (O); correspondence, 302, 426, 528, 738
Appeal tribunals, medical staffing of, 240
Appendicitis: Incidence in Sweden, 150—Probable influence of health education on improving mortality rate in (D. B. Armstrong), 277 (O)—Appendical mechanics and (annotation), 511—Three cases of prolonged faecal fistula following operation for (P. T. Crymble), 532 (O)
A.P.T.: keeping it cool and upright, 775
APTHORP, J. O. E.: Placental polypus, 230
ARCHER, N. (and E. SINGER): Successful treatment of influenzal meningitis with sulphonamides, 286 (O)
—— Col. Samuel Arthur, death of, 367
Ariboflavinosis, 645
Armour, Theodore Robert William, obituary notice of, 430
ARMSTRONG, D. B. Probable influence of health education on the improving appendicitis mortality rate, 277 (O)
Armstrong-Jones, Sir Robert, obituary notice of, 175
Army: Disciplinary cases, form of report by psychiatrists in, 5—Rehabilitation in, 337—Proportion of men rejected, 368—Vaccination in, 400—Medical regrading and employment in, 400—Proportion of men invalided for neurosis, 432—Education on venereal diseases, 553—Blood transfusion service, 610 *See also* Services, War
Arteriosclerosis, cramp in, 340
Artery, hepatic, a note on aneurysm of, with special reference to a rare cause of severe gastro-intestinal haemorrhage (G. Gordon-Taylor), 504 (O)
—— innominate, ligature of, 172, 301
Arthritis and intestinal streptococci, 654
—— rheumatoid: Soluseptasine for, 30—Peripheral nerves in (annotation), 640
Asbestosis and silicosis, medical board for, 368
Ascorbic acid, use of, in treatment of two cases of familial idiopathic methaemoglobinaemia (James Deeny and others), 721 (O)
ASHFORD, W. A. *Air Raid First Aid*, 541
Aspirin and gastric haemorrhage, 714, 768
Association for the Advancement of Psychoanalysis, New York, 208
Association, British Medical: Jubilee membership of husband and wife, 60—A member resigns (leading article), 135; correspondence, 200, 230, 267, 300, 332—And the Beveridge Report (leading article), 193; correspondence, 266, 299, 330, 362, 428—A safe milk supply; deputation to the Minister of Food, 265—A united front (leading article), 354—Consultation with Government on Beveridge Report, 359; Representative Committee, 359—Interdepartmental Committee on Medical Schools: memorandum of evidence, 702
—— —— Orthopaedic: Surgical treatment of osteomyelitis due to a penetrating wound (G. Perkins), 441 (O)—Military orthopaedics (special meeting), 483—And Empire Rheumatism Council: statement on prevention of crippling, 50; correspondence, 54, 111
—— —— of Physical Medicine, 621
—— —— Records: Memorandum on what records can be safely destroyed, 589
—— Capetown Postgraduate Medical, 621
—— Central Provident, 705
—— of Clinical Pathologists: Report of meeting and papers, 455
—— County Councils: Meeting with Minister of Health, 368
—— European, of Clinical Pathologists: Proposals for, 364—Inauguration of, 515
—— Family Planning, 644
—— of Industrial Medical Officers, 79
—— Mental After-Care: 63rd annual meeting, 298
—— of Municipal Corporations: Meeting with Minister of Health, 368
—— National, for Prevention of Tuberculosis: Closing of colony for boys, Burrow Hill, 589—26th annual conference, 641
—— Royal Medico-Psychological: Symposium on prefrontal leucotomy (leading article on), 510
—— Scottish National Blood Transfusion. Plasma drying unit opened, 464
—— Socialist Medical: Report of meeting, 339—Representatives' meeting with Minister of Health, 464
Asthma and other conditions in occupations and military service (E. M. Fraenkel), 216—*Physical Exercises for*, 4th ed., 287—In childhood (Sir A. Hurst), 403 (O); R.S.M. meeting on, 422; correspondence, 520, 550, 584—Psychological factors in (C. H. Rogerson), 406 (O)—Psychogenic factors in bronchial (leading article), 416—Sulphonamides in, 551—Treatment by nicotinic acid (G. Melton), 600 (O)—Theophylline for (annotation), 731
Atebrin, dose of, in malaria, 770
ATHOLL, Duchess of (and others): British Hospital for Stalingrad, 711
ATKINS, W. R. G. Vitamin C saturation test, 254
Atropine glaucoma (J. E. Martin), 631 (O); correspondence, 708
AUBERT, E. F. (and others): Withdrawal of blood for transfusion, 708
Austen, H. W. C., obituary notice of, 304
Australia: "Flying Doctor Service," 11
Avitaminoses in Middle East Forces, 375

B

Bacilli, saprophytic acid-fast, 455
—— typhoid, experiences of typing of, by means of Vi bacteriophage (A. Felix), 435 (O)
BACKWELL, M.: Teaching first aid, 82
Bact. typhosum type D4, an endemiological study (W. H. Bradley), 438 (O)
Bacteria, sulphonamide-resistant, 201
Bacteriophage treatment of bacillary dysentery (Arthur Compton), 424
Bagassosis and byssinosis (leading article), 46; correspondence, 110, 397
BAILEY, J. Shackleton: B.M.A. and Beveridge Report, 266
—— K. C. Amphetamine sulphas, use of, in facilitating electrically induced convulsions, 250 (O)
—— K. Vernon: A wheeled stretcher or equipment carrier, 542
Bailhache, Major Eric, death of, on service, 176
BAIRD, Dugald: Stillbirths and premature labour in hospital and specialist practice, 51
BAKER, Richard S. W. Lederle's pertussis antigen in treatment of whooping-cough, report of an investigation, 562 (O); correspondence, 678
Balantidiosis, a case of, 145
BALFOUR, Margaret: Nutrition in pregnancy, 297
BALLANCE, G. A.: Irritation of the urinary tract by "doped" beer, 540
Bandage, barrel, 589
BANKS, H. Stanley: Chemotherapy for meningococcal infections, 485
BANNISTER, Freda B. (and R. R. MACINTOSH): *Essentials of General Anaesthesia*, 353
Banting, Sir Frederick, notes on a book on, 448
BARBER, H. W.: Lupus erythematosis, 580

THREE YEARS OF MILITARY PSYCHIATRY IN THE UNITED KINGDOM

BY

J. R. REES, M.D.

Brigadier; Consulting Psychiatrist to the Army

The remark of Napoleon that "war is three-fourths a matter of morale; physical force only makes up the remaining quarter,"[*] if applied to modern warfare, might have seemed far-fetched to many of us in 1939. Now, however, we have lived through the day-to-day stresses and rituals of total war; we have watched and felt the successes and the failures of our own Forces and of our Allies; and, having dealt with men and women of all types under strain, none of us can doubt the general truth of this dictum. Probably it would be equally true if we said something similar about civil life in peacetime.

Certainly the sample of ordinary men and women who compose the Army in wartime have presented issues which have challenged psychiatric thought and practice. The Army doctor, perhaps more obviously than the civilian physician, concerns himself primarily with health and efficiency, and only secondarily with what one may call "salvage." The psychiatrist finds that in Army work his contribution to the total war effort is made far more effectively by varying prophylactic procedures than it could possibly be were he solely concerned with diagnosis and therapy. It may therefore be useful to present a general survey of the work of Army psychiatry, setting out its developments and present tendencies. Many excellent reports on clinical matters have been published from Army and E.M.S. hospitals, but no effort has as yet been made to give an inclusive picture of the work that is being undertaken in this country. Clearly, any attempt to do this in the space of an article for the *Journal* will leave out much that should be said, and there will be scope for separate reports on almost every topic when it is possible for these to be produced.

Pre-war Planning

The psychiatric problems of this war have, most fortunately, not presented themselves in the form that we had anticipated. Our pre-war planning, both for the Army and for the civil population, was based fundamentally on our 1914-18 experience, and we conceived that the stresses we knew then would be "hotted up" by incessant, relentless air attack on the civilians and the Army in this country. Reference will be made later to the incidence of acute war neurosis, but this has, in fact, been one of our minor problems.

We had at our disposal before the war the Report of the 1922 War Office Committee on Shell Shock, and the even more valuable Vol. X of the U.S. Army Medical History of the last war. Throughout the 1922 Committee report there is emphasis on the need for better recruitment and better selection of personnel. It stresses also that unstable and neurotic types do badly under any war conditions, and it emphasizes the need for early effective treatment and for medical training in the psychiatric handling of these men. The American Vol. X on Neuropsychiatry provided us with a complete textbook on both the clinical and administrative sides of Army work, and much of the history of our allies contained in that volume has repeated itself in the British Army in this war. There was therefore a considerable amount of material to aid us in making plans before the outbreak of war, and we were faced with one inescapable fact—that after 1918 there were over 100,000 pensioners with overt psychiatric disorders, quite apart from those men who drew pensions for psychosomatic illnesses which were given "organic" diagnoses.

Shortly before the outbreak of war a conference called by the Ministry of Pensions expressed the intention of providing treatment but not giving pensions, save in exceptional cases, to men who broke down with neurotic symptoms. This policy has to a considerable extent materialized, although up to date the moral situation which it was hoped to combat by this decision has hardly arisen, since there has been no epidemic of true war neurosis.

It was clear enough, however, that even before the outbreak of war the prophylactic approach to the problem was by far the more important, and that scientific selection and placing of men would do more than anything else to avoid the development of a large-scale problem. Unfortunately, it was not till much later that adequate measures could be instituted.

Two psychiatric consultants were designated for the Army before the outbreak of war, one for this country and one for the B.E.F. What concerns us in this account is the development of psychiatric work at home. This has been gradual and progressive, keeping pace with the numerical growth of the Army though influenced by the need for developing new techniques to meet changing situations. The Consultant, by himself in the first few months of the war, could do little more than see certain patients, lecture to the staffs of hospitals which were mobilizing and to groups of medical officers in training, make contact with the medical administrative services throughout the country, and begin to lay plans and develop the conviction necessary for them to be carried out.

Early War Measures

Early in 1940 specialists in psychological medicine were appointed to each command in this country. They very quickly found it impossible to get round their large areas, dealing with all the out-patients and with the other problems that they were asked to solve. Gradually more psychiatrists were added, either full specialists with the rank of major or "graded" specialists who had had rather shorter experience in the specialty, so that eventually there came to be in each command from three to ten area psychiatrists whose work was co-ordinated by the command psychiatrist at command headquarters. Their main task has been to provide an out-patient service for every area where there are troops or military hospitals. They visit units to discuss with regimental officers the military value of men who are referred to them, and to advise about a great many of the problems put up by units. They help in the selection procedure (this will be referred to later) and give a good deal of advice and teaching to unit medical officers over the handling of difficult men. More than any other group in Army psychiatry, area psychiatrists have succeeded in getting "inside the Army." They need to understand something of all the jobs, the training methods, and the intimate lives of soldiers. They have also to be very much *au fait* with all the administrative procedures and the techniques for disposal of the various cases that they meet from day to day.

---

[*] *Correspondance de Napoléon*, **18**, 14276: 1808.

Alongside the growth of this out-patient service came the growth of in-patient treatment. With the encouragement and help of the Boards of Control—help which has always been given most unstintingly to the Army—military hospitals were opened up for psychotic patients. In 1914-18 many difficult situations arose in which serving soldiers had to be taken to civilian mental hospitals; further, a large number of men in such hospitals were granted pensions which would probably never have been given had it been possible to make a closer investigation of the origin and constitutional nature of their illnesses. A mental hospital which is military as opposed to civilian can detain a patient without any need for certification, and a procedure has grown up in the Army by which officers or other ranks of either sex suffering from a recoverable psychosis can be kept in a military mental hospital before discharge for three or six or, in exceptional cases, nine months. This has the great advantage of allowing for effective treatment to be carried out while there can be thorough investigation of questions of attributability. The policy of the Army in this matter seems to have justified itself.

Most of the hospital treatment of psychoneurotic disorders has been provided by the special neurosis centres of the Emergency Medical Service, which have co-operated well with the Army. Inevitably, however, there had to be special wards in military hospitals. At first these functioned largely as observation wards or collecting centres, and gradually there have been developed special Army hospitals for neurotic disorders, which have the advantage over the E.M.S. hospitals of being military in their organization and atmosphere.

After the first eighteen months of the war it was becoming increasingly obvious that administrative procedures were fully as important as clinical or purely professional questions in Army psychiatry, and eventually early in 1942 a Directorate of Army Psychiatry was set up as part of the Army Medical Services, with a senior Regular R.A.M.C. officer as Director and three psychiatrists working with him. The Directorate is responsible for the development and control of the psychiatric services in this country and with the Over-seas Forces, and for the ever-increasing number of questions which are brought up for psychiatric help or opinion.

The Consulting Psychiatrist works with the Directorate, but is now freer to get round to commands and to undertake the various exploratory and co-ordinating jobs which come his way. He, like the other consultants to the Army, is an adviser to the Director-General, who has very wisely given his consultants much freedom of action.

Psychiatric Problems of the Army

The problems that have faced the Army have, from a psychiatric angle, been numerous. If continuous military action had been nearer to this country the problems might have appeared different, though they would fundamentally have been the same. Some may be puzzled as to why the Army should contain such a large proportion of men who have psychiatric problems; but the reason for this is not difficult to explain. Partly, there has existed for very many years a tradition that men who were immature or unsatisfactory, or whose social records were not above suspicion, could under Army discipline be made into "men." The Army in peacetime has always had a good many backward otherwise unemployable men, and in the majority of cases in the past they have turned out pretty well. Modern war, unfortunately, demands a different quality of man. A more important reason, however, for the accumulation within the Army of men whose mental background is questionable is that the man-power situation of this country has been so arranged that very large numbers of intelligent and able men are reserved in industry. The Royal Navy and the Royal Air Force have a priority of choice; and the Civil Defence Services have claimed a great many men. The Army comes last in the list, and consequently a large proportion of what has been called "the psychopathic tenth" of the country's man-power finds its way into the Army if the mesh of the recruiting boards is too wide. The Army has therefore to deal with very considerable numbers of dull, neurotic, and unstable men who have got on reasonably well in civil life, whenever employment was plentiful: thrust into the stresses of Army life, they become difficult in various ways. These no doubt are the men who, when times are hard, become a problem to the National Health Insurance scheme and to the Ministry of Labour; and very many in the same group would after the last war have found themselves on the books of the Ministry of Pensions. One of our aims has been to avoid repetition of the pension situation which arose after 1918.

Recruitment

It is possible that there has been insufficient understanding and inadequate co-operation between the medical officers who have given so much good service on the recruiting boards and medical officers in the Army. At times there has certainly been a feeling in the minds of some of the medical officers in the Ministry of National Service that the Army's standards were too high and that in consequence too many of the men they had passed in were being boarded out and sent back to civilian life: and here we are concerned, of course, only with the cases in which there is some psychiatric disability. It is perhaps more important, however, to record the great difficulty in recognizing and assessing the neurotic constitution and the intellectual status of men in the short time that they are before the boards, even for board members with a specialist training, and still more for those who have not had special experience. The introduction of intelligence testing at the time when men are called up for their medical board examinations appears to have been of help to the boards in the detection of some of the men whose dullness was hidden by a good façade. Better liaison between the boards, private doctors, and the School Medical Service would probably have been valuable. On the whole the neurotic man, more than his defective fellow, tends to give a reasonably truthful account of himself and his disabilities to a doctor. There is, of course, the obvious difficulty that such a man, fearing military service, may exaggerate or even make quite untruthful statements about himself in order to prevent his calling up. The other danger is that men wishing to join up may give too rosy a picture of themselves, and later on, finding themselves in difficulty, may then take the opposite line and "tell the tale" in order to get out of the Army. These are universal tendencies that nothing is likely to eradicate. If we had no shortage of man-power it would clearly be better rigidly to exclude any men who were not cheerfully prepared to give their services; in this country, however, we have never been in that happy position. Only improved understanding and better investigation can meet the problem of decision about the less willing and the relatively rare instances of the unwilling soldier. It is certain that, in recruiting, a penal attitude, such as occasionally has emerged in the statement that "no one must be allowed to get away with it," is not likely to produce the Army we should all like to see.

At the present juncture it is inadvisable to give exact figures or percentages of the psychiatric disabilities, apart from the classified figures which have already been published of limited groups in hospitals in this country. It is permissible, however, to say that the invaliding or discharge from the Army from all psychiatric causes has been approximately one-third of the total invaliding, a figure which is comparable to the incidence of psychiatric illness in civil life in this and other countries.

Intellectual Defect

There are many fallacies which creep into the assessment of defect by intelligence testing, and the estimation of mental age is by no means a straightforward matter save in the hands of very skilled workers. Broadly speaking, it has turned out during this war that few men whose mental age is below 10½ are fit for Army life except in special unarmed labour sections. It would be folly to attempt the placing or rejection of men simply on the basis of an intelligence test, whatever the safeguards; and, in fact, no one in the Army ever has been recommended for discharge solely for this reason. Investigation of the social and employment histories of all men is essential, and a general psychiatric assessment is made in each case. In the modern Army there are far fewer simple routine jobs than there were in the old Army with its "horse lines" and its slower tempo. There still are plenty of vacancies for the not-so-bright man in the modern mechanized Army if he is properly placed; but unless he is recognized and fitted to an appropriate role he is likely to become a consumer of man-power rather than a strength to the Army. The dull man is a drag on training and rarely becomes efficient in any technical task. He feels himself out of things and hence inferior; he gets anxious and breaks down far more easily than a man of normal intelligence, and, through difficulty in morale-development and failure to understand regulations and the reasons for them, he is extremely liable to Army crime. The United States Army demonstrated in the last war that the worst soldiers were often the best diggers, a fact once more convincingly demonstrated in the British Army in this war.

Whatever the exact incidence in the ordinary population of the country of those groups who have a low capacity to learn—the dull and backward, the feeble-minded, the imbeciles, or idiots whom Prof. Burt in one inquiry totalled at 25.1% of the population—it is clear that they are numerous. The men with the greatest degrees of defect are for the most part recognized and excluded from the Service by recruiting boards. There remain, however, some 8 or 10% of the whole Army intake who need special consideration in their employment; approximately 2% of these are men who, after a short trial period in the Service, may well turn out to be impossible of employment in any combatant or operational role. The dullards, with whom the Army has had so much concern, might many of them well be called "one-job" men. They have very often found niches for themselves in civil life where they have been able to give first-class service on one particular routine job. If a similar or an equally appropriate niche can be found for them within the Army, then their work can be of great value to the war effort. Experience has shown that where they go unrecognized and are put in units of ordinary men they quickly begin to present problems.

The employment of those men who have a very low capacity to learn but who can be expected to remain emotionally stable in unarmed labour sections has been notably successful. Without this provision the majority of them would have been lost to the Army, and some would have been unemployable in civilian life even in the present time of labour shortage. In these special groups, with wise officers and N.C.O.s, they give splendid service in a variety of occupations, relieving more intelligent men for other tasks and in many cases doing the jobs very much better than they are normally done by the more intelligent type of individual. These men are proud to be in the Army, and they are happy because they have found friends on their own level. Disciplinary troubles are almost entirely absent, and these units provide a striking indication of what can be done in the way of employment of a group in society which in pre-war years had certainly been a problem from many angles.

The women with an equally low capacity to learn seem on the whole to be rather more stable and to be less inclined to break down; but they too present a problem in Service employment, and, in fact, for some time past those who on preliminary intelligence tests fell into the lowest 10% of the population were not taken for service in the A.T.S.

Illiteracy by itself does not prove a bar to military service, though clearly so long as it persists it would exclude men from many units in which they might find themselves in a responsible position that demanded literacy. Approximately 50% of the illiterates are intellectually defective, while the other 50% come from specialized groups such as barge-workers and gipsies.

Selection

After the failure of a pre-war attempt (March, 1939) to get selection-testing introduced into the Army, it was clear that the psychiatrists would have to begin weeding out unsuitable men, and in the first year of the war a good many were transferred to labouring jobs, though after Dunkirk this was stopped for a time. After much discussion it was decided to start special groups for men who were not fit to bear arms, and consequently the number of those who have to be discharged from the Army on grounds of intellectual defect has fallen as the facilities for their employment within the Army's structure have improved. In 1940 the psychiatrists who were then at work in the Army began to employ such familiar methods of testing as the modified Binet-Simon test and the Herring revision. Kent's oral norms, Koh's blocks, and a number of other tests were brought into use, and the Penrose-Raven matrices were employed on an experimental basis. The matrix test proved to be particularly valuable, being a non-verbal method. In 1940, with Dr. Raven's help, it was introduced as a group intelligence test at one of the R.A.M.C. depots, and its careful standardization and validation was begun. As a group test it proved to be extremely useful. It was possible to squad men for training according to intelligence, and the lower group on the intelligence scale were very properly referred for psychiatric interview, as also were those who made unreliable scores, often for some reason connected with instability. A little later on, through the Director of Military Training and the Army Education Corps, a series of verbal tests was introduced under the guidance of Mr. Farmer of the Cambridge Psychological Laboratory; these were widely employed, and when properly used proved valuable. In June, 1941, after much preliminary work, a Directorate for the Selection of Personnel was set up under the Adjutant-General, and its work, guided by industrial psychologists of experience, has accomplished a great deal for the efficiency of the Army and for safeguarding mental health. The matrix test was introduced at all recruiting boards. Large groups of men whose work in the Army was being changed were put through group tests and given a percentile rating in relation to the whole population. Recently, since conviction of the value of this work had grown sufficiently, the administrative difficulties were overcome and the General Service selection procedure was introduced into the Army at the beginning of July, 1942. All men are now taken into the General Service Corps, where alongside their basic training they are put through a battery of intelligence and aptitude tests, interviewed by specially trained officers, and posted to the most appropriate possible duties in the Army.

The Directorate for Selection of Personnel had undertaken a complete job-analysis of the multitudinous tasks in the different arms of the Service, and as a result was able to lay down the standards of intelligence and other aptitudes necessary for each job, thus providing a basis for the correct posting of men in certain proportions to each type of unit. The accomplishment of this work produced a revolutionary change in the Army's utilization of man-power and has set a standard which will certainly be applied in industry and in social life in the post-war world. The matching of men to suitable work is as valuable a means of psychiatric prophylaxis as anything that could well be devised.

In this mass selection of men psychiatry is perhaps the handmaid of industrial psychology, whereas in other fields—e.g., officer selection and with other groups in which temperamental factors must be assessed—psychology is the handmaid of psychiatry. In fact, in the Army the psychologists and the psychiatrists work together as a team in the best possible way, and their interdependence is fully demonstrated. The accompanying diagram showing the lay-out will be of some interest. In dealing with large groups of men who are put through the General Service selection procedure, in which a battery of intelligence and aptitude tests are employed, the psychiatrist sees all those men who are low scorers, and in addition all whom the trained personnel selection officers regard as unreliable or puzzling, whatever their intelligence. In this way many of the potential psychiatric problems are brought to light at the very beginning of Army life, and it is possible to ensure the wisest employment of these men within the Army machine.

Table showing Details of Disposal Recommended by Area Psychiatrists for All Cases Examined as Out-patients during the Six Months preceding April 30, 1942

Recommendations	Referred through Personnel Selection	Referred through Unit Medical Officers				
		Neurosis and Psy. Pers.	Dullness and Defect	Psychosis	Other Diagnosis	Total
Return to unit: no action ..	14,374	1,844	2,127	9	1,485	19,839
Observation in unit ..	1,040	1,701	48	21	374	3,184
Out-patient treatment	883	375	9	6	52	1,325
E.M.S. neurosis centres ..	68	3,291	28	59	108	3,554
Army neurosis centres ..	16	1,502	7	27	19	1,571
Army mental hospitals ..	47	529	6	742	81	1,405
Other hospitals ..	28	350	5	58	270	711
Reduced category	213	1,788	81	17	106	2,205
Pioneer Corps, including unarmed sections ..	12,504	563	3,365	8	83	16,523
Other corps ..	3,832	786	853	1	208	5,680
Other disposals ..	1,579	1,123	401	46	811	3,960
Discharge ..	1,180	3,786	1,108	114	260	6,448
Total ..	35,764	17,638	8,038	1,108	3,857	66,405

The figures set out in the accompanying Table, of work done by area psychiatrists in the period just before the introduction of the General Service scheme, give an idea of the types of disposal recommended or advice given in these psychiatric interviews. A detailed discussion of these figures will be the subject of a further paper.

Psychosis

Reference has already been made to the organization of special mental hospitals within the Army. There are ten of these. For the most part they are in separate blocks of civilian mental hospitals, taken over by the Army and renamed. The superintendent of the mental hospital and his deputy are given honorary rank for disciplinary purposes, and the superintendent is O.C. the military hospital. The number of beds in these units varies from 74 to 400. Medical staffing is, so far as possible, on the basis of one Army psychiatrist to 50 patients. Fortunately these beds have never been completely filled, although certain units have worked under great pressure with a very big turn-over. The incidence of psychosis has been less than was anticipated, and constitutes a small though important part of the psychiatric work of the Army. The R.A.F., our various allies, and the prisoners of war have to be accommodated, and one hospital is entirely devoted to officers and other ranks of the Women's Services. The average duration of stay in hospital for psychotic cases is about 75 days, and the results obtained by active treatment—continuous narcosis, shock therapy, insulin, P.T., and occupational therapy—are good. As in the Middle East, there seems at home to be some evidence that psychotic breakdown in the Services clears up rather more quickly and satisfactorily than in the equivalent age groups in civilian life. Some 95% of the psychotic patients in military mental hospitals are returned to the care of relatives as recovered or to public assistance institutions, while the remaining 5% are discharged to civilian mental hospitals. In this way it is clear that one purpose of these hospitals has been realized and that the civilian mental hospitals have been saved an additional burden. A follow-up scheme is at present being devised so that we may learn the after-histories of these patients in so far as further breakdown is concerned. Three of these hospitals are staffed entirely by mental nursing orderlies (male). There has been some difficulty in getting for this type of work enough nursing sisters of the Q.A.I.M.N.S. with a double qualification.

A new classification of mental disorders is now about to be adopted by the Army after much deliberation, and it should help in clarification of statistical returns when these come to be made at the end of the war.

Neurosis

The "psychopathic tenth" of the population, who, as was said above, so largely find their way into the Army, provide us with a very considerable number of men and women who are constitutionally predisposed to neurosis and whose histories reveal evidence of chronic neurotic tendencies from childhood. In active warfare some of these men might have carried on and given good service, as some such men no doubt did in the last war. The inaction and relative monotony that have been forced on so many units of the Army in this country have tended to bring out neurotic tendencies which already existed, and much of our work in Army psychiatry has been concerned with such cases. Only a small proportion of these men are likely to benefit by hospital or out-patient treatment sufficiently to warrant their being kept in the Army. In civilian life they were able to carry on in their own particular niches, going to the doctor when they felt it necessary. The very fact of giving up their individuality and becoming cogs on a large wheel appears to weaken resistance to their own emotional difficulties. Separation anxieties affect most men in the Army to some extent; while boredom, which is at times almost inevitable, produces an immediate increase in sickness rates, neuroses, and disciplinary troubles, which are, indeed, indices of bad personal and group morale.

The special neurosis centres of the E.M.S. and the hospitals devoted to these cases in the Army have all of them found that one of the main difficulties centred round the problem of individual morale. It has recently been decided to attempt a rough classification of these men according to the probability of their return to the Army, and to devote particular hospitals to them, while those who are more likely to need rehabilitation and discharge to civil life go to other hospitals. The constitutional neurotic certainly reacts badly to the close proximity of a medical board with a steady trickle of discharged men leaving the hospital in metaphorical bowler hats.

A good deal has been written, particularly from E.M.S. hospitals, about the clinical work with these cases, but little that is new has emerged save a modified insulin treatment which helps on the physical side, and some experimental work in occupation which seems likely to prove valuable in wartime. In a hospital for neurotics the ordinary methods of occupational therapy are less appropriate than military occupations. There are Army physical training instructors in each of these hospitals, including the E.M.S., and military training with various modifications is being used with considerable advantage in certain of them. The principle behind this is that to learn to strip a Bren gun properly may be more valuable than to learn carpentry or rug-making, since it is obvious that a patient who recovers is in a stronger position if he can go back to his unit direct from hospital as a fit man who has had further military training than if he needed a convalescent depot for hardening before his return to duty. Whenever it has been possible, spare-time occupations that have some relation to the war effort have been tried, such as making toys for children in day nurseries and the use of simple machines which assist in such work as is admissible in a hospital under the Geneva Convention.

So far as concerns the men who return to duty in the Army, there is a follow-up system which makes periodic inquiry regarding the men's military efficiency and their fitness, and the figures thus provided form some guide to the accuracy of the clinical judgments made in the various hospitals.

Unfortunately as yet there is no means of following up the progress of those men who have been discharged and gone back to civilian life. Despite all the difficulties in the way, after visiting the various hospitals one is always left with the impression that something of value is done even for this group of men who cannot fit into the Army, and that in consequence they may, as a socio-medical group, be rather less of a problem in the future.

An extremely useful experiment in the placing of men occupationally has been carried out for the past eighteen months. Those patients who after treatment in hospital are considered unfit to go back to the units from which they came, but who in the opinion of the doctors have a good chance (75%) of giving efficient service to the Army in some special trade or in some special job which is in line with their pre-war interests or abilities, can be appropriately posted. Each of the neurosis centres and special Army hospitals has direct access to the War Office about these men, and the follow-up inquiry carried out by the administrative branch concerned shows that only 9% of the men so dealt with have turned out failures, while over 70% have been very successful. This figure deserves, and is to have, a more careful check made in the near future. This large-scale individual employment agency is certainly providing a very valuable method of rehabilitation as well as maintaining the man-power of the Army.

As would be expected, the tale of the acute war neuroses resulting from enemy action is very much more cheerful. Since a large number of these men have a good constitution and good medical records the results have been very satisfactory wherever treatment has been undertaken early. Men from Norway and Dunkirk who broke down as a result of prolonged stress have for the most part been got back to duty satisfactorily, many of them to full combatant status. It is a matter for much regret that many men were invalided back either with wounds or with physical diagnoses, and consequently in general hospitals their anxiety tended to go unrecognized, with the result that no specific treatment was provided until the condition had become almost ineradicable. The physical and psychological methods employed, which have proved necessary and valuable in this country, have been fully described in the medical press. In the Middle East Forces the results of treatment seem to have been still better, as one hoped.

Education

The first psychiatrists selected for work in the Army were chosen partly on the grounds that they were experienced teachers who could when necessary give formal instruction and could more often teach without any special appearance of so doing. A satisfactory proportion of the large number of men and women psychiatrists who have later been appointed have shown themselves well able to carry out the same important functions.

The numerous contacts of Army psychiatrists give them day-to-day opportunities of discussing with regimental, legal, and administrative officers problems of morale, discipline, training, "man management," and other topics bearing on mental health. A great number of formal lectures have been delivered to small and large groups in Divisions, Army Schools, H.Q. Conferences, etc. Lectures on psychiatric work in the Army are given to M.O.s in the depots when they are beginning their Army career and on various other occasions later on. Some short systematic groups of lectures have been given and regular tuition has been provided at some E.M.S. and Army hospitals. Further attempts are being made to keep every M.O. of the Field Force *au fait* with the latest methods of dealing with true battle neuroses.

The shortage of medical man-power emphasizes in every branch of the profession the need for specialist training, and in none more than in psychiatry. At one of the Army's special hospitals for neurosis the sixth course (now of three months' duration) is just being completed. Courses of this length cannot produce specialists; but they can widen a previous experience in psychiatry, and they can make a well-balanced M.O. of good general experience a better Army doctor or even start him on a most useful career as a "psychiatric assistant" so that he may ultimately become a specialist. All Army psychiatric hospitals at home and abroad are approved for resident experience for the D.P.M.

Every type of psychiatric experience and approach is of value in the Army once it has been broadened or deepened where necessary and the essential military orientation has been developed.

Medico-Legal Work

It is most satisfactory that the relationship between psychiatrists and the Judge Advocate-General's Department is increasingly one of understanding and co-operation. Medicine and the Law have often been at cross-purposes, and such a situation would be disastrous in the Army. Military crimes are easy to commit, and especially is this so for the dullards and the neurotics. We have aimed at avoiding conflicts of opinion, waste of psychiatric time through appearance at courts martial, and the undertaking of legal procedures in psychiatric cases, where no good purpose was likely to be served either for the group or for the guilty individual.

Much discussion has resulted in an agreed pro-forma (here reproduced) for use by the psychiatrist in reporting. This is

FORM OF REPORT BY PSYCHIATRISTS IN DISCIPLINARY CASES

This report is intended as a guide for the Commanding Officer in considering disciplinary action where the question of the accused's fitness to plead, sanity, and responsibility has been raised. Where in the opinion of the psychiatrist a man is clearly fit to plead and clearly responsible for his actions at material times, a brief report to this effect may replace parts B and C of this report. If the accused is remanded for court martial this report must accompany the application for court martial. The Convening Officer should submit the papers including this report to an officer of the Judge Advocate-General's Branch before ordering trial.

(iii) Any other relevant information:

sent to the convening officer, whose responsibility it is to decide whether a court martial shall be held. The psychiatrist is thus in every case playing his proper part as expert for the Crown—briefed neither by prosecution nor by defence. This scheme works well. The J.A.G.s often attend and take part in psychiatric meetings in commands. The close contact thus established makes it possible to discuss difficult cases, to the benefit of both professions.

Arrangements exist whereby dull men in need of psychiatric care or disposal after the court martial are notified, and the detention-barrack problems are thereby eased.

Social Psychiatry

Very largely because of the excellent and close co-operation with industrial psychologists it has been possible to achieve a number of advances in social medicine and prophylaxis in the Army. The efficiency of the Army for the primary purpose of winning the war is the concern of everyone, and from this angle prophylactic measures are infinitely more important than the provision of treatment, valuable and interesting as that is. If any demonstration were needed that the neurotic tendencies of men can be best controlled when they are doing suitable work, that proof has certainly been provided by the scheme for misfits mentioned above. The personnel-selection work of the Army is a major contribution to its mental and physical health as well as to its fighting efficiency and out of the present General Service procedure it seems probable that there will develop a method for use in industrial selection in the future and for the sorting of any large groups of men or women.

Army psychiatry took the initiative in investigating and applying tests for personality and character studies. From this work has developed the specialized technique of the War Office Selection Boards for choosing officer candidates. Here selection is made after two days of observation by a team reminiscent of a child guidance clinic! The team consists of the president and military testing officers (regimental soldiers), psychologists, and psychiatrists. It is not surprising that the character assessment made as a result of the psychiatric interview is in many cases the most valuable of all the various opinions which are presented to the final board before its verdict is given. At present these boards are aiming to discover certain qualities which are particularly necessary for a good officer in different arms of the Army. Follow-up work has been undertaken, and this it is hoped will be carried on right through the Army service of each of these men. It seems as though there had been established a valuable principle for the selection of specialists for various professions and occupations, though for each particular group special techniques will have to be scientifically designed. There has been, and will still be in the future, much resistance to be overcome before the principle of selection by scientific procedure is accepted. Selection pays, but it also carries a threat; for the more accurate it becomes the more it explodes the pleasant and universal fantasy that each of us has a Field-Marshal's baton in his knapsack.

War aims are necessary for us all, and psychiatry has certainly some visions of what can be brought about after the war and where it can slowly but surely make a very considerable contribution to the national life.

Psychiatrists in the Army have not been content to stop short either at clinical psychiatry or at selection, and fortunately they have increasingly been asked to give help and advice with a large number of other problems, such as the multitudinous aspects of morale. In nearly all of these problems there is some way in which the psychiatrist, thinking in terms of the emotional life, can give useful help; later he has the satisfaction of realizing that once his plan has been grasped and carried out it is regarded as "just common sense." In military training there are many problems which concern the industrial and educational psychologist and many in which the psychiatrist also can assist. Accustoming or "inoculation" of men to those battle stresses that menace morale has been one main way in which psychiatrists have helped. To give guidance on questions of the stirring up and effects of hate, on "debunking" battle noise, the tank, and the morale-destroying aspects of the dive-bomber and other alarming techniques of war, makes a very sure contribution to the mental stability and the battleworthiness of men under training. In these and many other ways psychiatry is concerning itself with the task of the Army just as it is concerned with the health of individuals and groups through wiser disposal and posting and through its experiments with the constitutional neurotic and the dullard.

From all these lines of work there open up further possibilities for help to the Army during this war and to the community after it.

My thanks and acknowledgments are due to Lieut.-Gen. Alexander Hood, D.G.A.M.S., for his permission to publish this article, and still more for all his support and backing; to Major-Gen. S. Kyle, who in 1939 gave to the three consultants then appointed at home the opportunity to contribute to the war effort and to the efficiency of the Army; and lastly to my colleagues who, "conspiring to win the war," have by their thorough grasp of matters military, medical, and sociological provided the ideas and the drive for the work of Army psychiatry.

OBSERVATIONS ON INJURIES TO THE SEMILUNAR CARTILAGES IN SERVICE PATIENTS*

BY

S. ALAN S. MALKIN, M.B., B.S., F.R.C.S.Ed.
Surgeon-in-charge, Harlow Wood Orthopaedic Hospital, Nottingham

The object of this paper is to analyse the facts obtained as a result of treating injuries to the semilunar cartilage and to see whether any useful information can be drawn from them. The observations are the results of the combined work of the staff of the Harlow Wood Orthopaedic Hospital.

From the beginning of the war until April, 1942, there were admitted and discharged from the hospital 185 patients suffering from injuries in the region of the knee-joint (excluding wounds and fractures). These were diagnosed as follows:

Synovitis	9
Strain (various types)	16
Pre-patellar bursitis .. .	1
Semimembranosus bursitis ..	2
Subsartorial bursitis	1
Loose bodies	3
Dislocation of patella ..	3
Osteo-arthritis	7
Post-operative cases (I D.K)	8
Injuries to semilunar cartilages	135

In times of peace some men, as a result of athletic activities, injure their knee-joints, and, unless they are professionals, give up the game in which they have been injured and may be able to carry on without very serious disability. It is probable, therefore, that only a small proportion of these cases are ever seen by surgeons and have surgical treatment. In wartime, however, those who are unfit to do what is required of them in the Services must necessarily report sick, and sooner or later they are referred to an orthopaedic centre for advice and treatment. It may therefore well be that the incidence of the various lesions in injured cartilages in Service practice differs widely from that in civilian life.

An inquiry into the position in wartime has been made possible by the establishment of these special orthopaedic centres, in which relatively large numbers of certain types of case, including injuries to the knee-joint, have been segregated. With uniformity of hospital records and notes which this segregation makes possible, it is easier to analyse cases than it would be in peacetime, when notes covering many years, written by different individuals, have to be examined.

---

* Read at the autumn meeting of the British Orthopaedic Association at Nottingham, September, 1942.

The number of cartilage cases here reviewed is relatively large, as all have been seen in a comparatively short period. Many are still fresh in our minds, and can therefore be compared and analysed with reasonable accuracy. The cases actually treated by operation numbered 131, and 136 cartilages were removed. The types of lesion found were as follows:

Internal Cartilages	99	External Cartilages	31
Bucket-handle	38	Bucket-handle	5
Posterior tear	28	Posterior tear	5
Anterior tear	11	Anterior tear	8
Intermediate	15	Intermediate	4
Hypermobile	6	Cysts	7
Cysts	1	Disks	2

No demonstrable lesion, 6 (3 internal, 3 external)

It is interesting to note that the internal cartilages were to the external as 3 is to 1, and that there was one cyst in an internal cartilage and in external cartilages there were seven. These figures roughly correspond to those expected in civil practice, although the number of external cartilage lesions is much higher than was formerly thought to be the case. In only four instances were two cartilages removed from the same knee-joint, and in only two of these were two lesions found: the one point of interest here is the comparative rarity.

Eight patients had had operative treatment elsewhere and were brought into hospital because they had not subsequently made good progress. In six of these the main disability was due to quadriceps insufficiency.

Diagnosis

The first essential is an accurate history, the chief points of which should be the type of injury, the immediate effect of the injury, the length of time taken in recovery and, if this is complete, the number of recurrences, and finally the sensation of the patient regarding the stability or otherwise of his knee.

The second essential is an accurate clinical examination. Here the facts to note are the points of tenderness; the existence of a click which may be elicited at different positions in the range of movement of the knee-joint, the presence or otherwise of locking, and pain at the extremes of movement. The diagnosis depends, therefore, on a combination of the clinical findings and the history, and a negative radiograph. Some patients come with their diagnosis ready-made; they give a definite history of locking; but it is sometimes not easy to realize that their ideas of locking and ours are totally different.

Using these methods, in 6 out of 136 cartilage operations no demonstrable lesion was found. Why was this so? In most cases the history was definite but the clinical findings indefinite. In one case an effusion prevented an adequate examination. In another, arthritic changes were present in the joint. In practically all instances the diagnosis might have been cleared up by a period of intensive and controlled physiotherapy. In doubtful cases we therefore now subject the knee to intensive work so that its reaction may be noted. Six cartilages were thought to be hypermobile at the time of operation. In all of these cases the diagnosis and clinical examination seemed quite definite, and we consider that a mobile cartilage should be recognized as a clinical entity. These patients made normal progress after the cartilages had been removed, and those treated to a conclusion at the rehabilitation centre were quite satisfactory. All were internal cartilages.

In the first part of the period under review we were not able to treat cases to a conclusion. The patients left the hospital after three or four weeks and were lost to us. Our experience with cases from other areas made us feel that possibly our own, too, might not be making the progress we expected. We felt very dissatisfied with the position, and because of this we decided to establish for ourselves a rehabilitation centre at our Lound Hall Annexe. When this was established, patients, instead of being sent away with instructions about post-operative treatment, went to the rehabilitation centre and remained there until their treatment was completed. This centre is able to take 50 patients. The staff consists of an Army P.T. instructor and a fully trained masseuse, and visits are made at regular intervals by a member of the surgical staff of Harlow Wood Hospital. The cases can therefore be divided into two series; the first consists of those treated before the rehabilitation centre was opened, the second series comprises those treated after it had been opened. (In discussing the results of treatment only those in the second series will be referred to.)

Treatment

There are certain points in the operative treatment which we consider important: (1) A small incision about 1¼ in. into the joint. (2) The removal of the whole cartilage—i.e., not merely the detached part. (3) Immediate post-operative treatment, consisting of active contraction of the quadriceps (quadriceps exercises should be learnt before the operation). (4) Continuous physiotherapy, consisting in the main of active exercises, which should not be too strenuous to start with. These should conclude with cross-country runs, long walks, and ordinary games.

It has been interesting to observe that patients whose treatment was discontinued on account of their going home on leave on compassionate grounds sometimes came back with the quadriceps less efficient than when they left. We believe this was because they ceased to do their regular exercises. They are now instructed to put half a brick in their tin hats and hang these over their ankles, and so do resistance exercises while on leave. The result of this simple instruction has been a decided improvement.

Results of Treatment

Since the opening of the rehabilitation centre, during the period under review, 86 cases have been treated to a conclusion. In 70 of these (81%) the time varied from 6 to 9 weeks, with an average of about 8 weeks. This probably errs on the long side, as some were certainly fit to leave the hospital a few days or more before they were discharged, but had to wait for posting orders. Sixteen patients took 12 weeks or longer. There were various reasons for this. Six had a persistent post-operative effusion. Most of these were in the rehabilitation centre about the same time, and we are inclined to think that they may have had too much treatment in the early stages and were straining their knee-joints. We have accordingly given up the use of weights and pulleys except as a weekly test to show the progress that has been made in the re-education of the quadriceps. In three cases two cartilages were removed, and there was an interval between the two operations. One patient had a partially calcified cartilage, one a semimembranosus bursitis, one tonsillitis, and one a generalized skin infection; and in three there were arthritic changes in the joint. There was therefore at least a partial explanation of the delay in each instance.

Long-standing Cases.—In 12 cases there was a history of the disability having extended over five years or more. It was interesting to see whether, in these cases, any one particular lesion was usually present. The lesions found, however, were varied. Four were of the bucket-handle type, two were posterior tears, one was a cyst in the internal cartilage, three were anterior, and two were intermediate. While, of course, it is impossible to say whether these patients had suffered from a lesion of the internal cartilage during the whole of the period for which they gave a history of disability, it is worth noting that in only three were there signs of arthritic changes in the joint. These patients were aged 24, 39, and 40 years.

Osteo-arthritis.—This was seen radiologically or at the time of operation in 11 cases. The average duration of treatment in these cases was 10 weeks. This, however, was increased by two cases of the previous series. If these cases are excluded the average duration of treatment was 8¼ weeks. It appears that arthritis in a mild degree does not seriously interfere with post-operative recovery.

End-results

Of the patients included in the second series 4 had medical board examinations and were placed in Category C. The remaining 82 returned to duty in their original categories, so far as we are aware. As a check on these results inquiries were sent to the Regimental Records regarding the whole of the patients (Series I and Series II), and definite replies were received in respect to 78 patients. These were divided as follows:

Series I (Pre-rehabilitation)		
Definite replies to letters of inquiry		31
Graded A1	14 (45%)	
Discharged from Services	6 (19%)	

Series II (Post-rehabilitation)	
Definite replies to letters of inquiry	47
Graded A1	36 (77%)
Discharged from Services	2* (4%)

* One aged 45 and one non-cooperative when in hospital.

These figures do not, in themselves, prove anything, but they are an indication that the cases treated to a conclusion (Series II) have done much better than those discharged without this extension of treatment.

Conclusions

The policy of the Emergency Medical Service in segregating cases of certain types in special centres has made it possible to survey a large number of Service cases in a short period, and from them certain observations have been made:

(*a*) That a major cause of disability following removal of semilunar cartilages may be quadriceps insufficiency.

(*b*) That in long-standing cases no one particular type of lesion was found, nor was there any definite relation between the development of arthritis and the length of the disability.

(*c*) That arthritis of a mild degree has little effect on the length of post-operative treatment.

(*d*) That post-operative rehabilitation at a special centre is of the utmost value in ensuring the satisfactory recovery of Service patients.

(*e*) That operative treatment for lesions of semilunar cartilages in Service patients is well justified.

MITRAL SYSTOLIC MURMURS

BY

WILLIAM EVANS, M.D., F.R.C.P.
Physician, and Assistant Physician to the Cardiac Department, London Hospital

Disagreement on the significance of certain systolic murmurs in the mitral area has imparted to these an ambiguity which has caused them to hinder as often as help in the diagnosis of heart disease. When electrocardiography and cardioscopy (radiological examination of the heart) were first enlisted as accessory methods to implement physical signs in the recognition of cardiac disorders, there was born a tendency to regard them as the principal tests and not as useful aids. This view gained a fillip from the uncertainty identified with the interpretation of added heart sounds and murmurs. Correlation of physical signs and radiological findings through the intervening years, however, has given to murmurs their true significance in terms of altered heart structure, and it is now possible to recognize, by clinical examination alone, most of the conditions which produce abnormal auscultatory signs. Of course, cardioscopy will continue to have great value in confirming the clinical impression, sometimes modifying or correcting it, and always showing the extent to which the disease alters the size and shape of the individual heart cavities.

Special Features of Mitral Murmurs

The need to recount the special features which characterize mitral murmurs receives emphasis in several departments of medicine to-day. Thus, in children the incidence of an innocent systolic murmur is high, and a faulty interpretation of this auscultatory sign is commonplace, condemning many of them unnecessarily to a life of semi-invalidism; routine medical examination of school children has inevitably subscribed to this episode. It should be a rule that no child is denied games and the healthy activities inseparable from a happy school life on account of a heart murmur of doubtful significance. Directly this suspicion has rested on a child arrangements for a special examination at a cardiac centre should operate automatically. Only in this way can unwarranted cardiac invalidism in children be avoided. Again, a young subject during convalescence from acute rheumatism is often confined to bed for several months because an innocent systolic murmur has been regarded as evidence of endocarditis or as a sign of mitral disease.

Medical examination of recruits before admission into the Services provides another circumstance in which the mitral systolic murmur is frequently misinterpreted. Thus, a subject with an innocent murmur may be rejected and classified as Grade IV, and another with a murmur signifying organic disease accepted into Grade I. The same problem may present in the case of young adults in civilian occupation during the medical examination admitting them to a life insurance: in none should the premium be "loaded" on the grounds that a murmur is present, unless it can be shown that it stands for a structural change in the heart. Again, a systolic murmur in the mitral area may loom prominently in older adults involved in a claim for compensation in respect of an accident, when the significance of the murmur will be debated in relation to the injury incurred. Then it is time to issue the warning that during the demobilization of members of the Services at the conclusion of hostilities none shall be awarded disability pension on the flimsy evidence of a murmur in the heart or in respect of the mischievous caption of "V.D.H."

For these reasons it is clear that there is need for an evaluation of this auscultatory sign in the diagnosis of heart disease and for examining the distinctive features which may identify a murmur with some precise cardiac disorder. A discussion of the subject is facilitated by assembling the several murmurs in three groups.

The Irrelevant Mitral Murmurs

The murmurs included in this group are easily recognized as a rule, and, since they usually display their main characteristics in some other auscultatory site, in relation to the mitral area at least they may be classed as irrelevant. A detailed description of these murmurs is therefore unnecessary, and little more than their mention will be made here. The *conducted* murmurs of congenital pulmonary stenosis and patent ductus arteriosus are best heard in the pulmonary area, and that of ventricular septum defect at a point internal to the mitral area. The *haemic* murmur in anaemia is associated with one in the pulmonary area; it is seldom so loud in the upright as in the reclining posture, and as a rule it is soft in character, although sometimes it may be rough and resemble the characteristic late diastolic murmur of mitral stenosis; successful treatment of the anaemia annuls the murmur. A systolic murmur may often arise from the cardiac *displacement* witnessed in pulmonary fibrosis, considerable pleural effusion, pneumothorax, and conspicuous depression of the sternum. In *tachycardia* from any cause, especially if accompanied by pyrexia, a mitral systolic murmur may appear, and disappear when the pyrexia subsides and the heart slows.

The Innocent Murmur

Misinterpretation of this murmur, which is commonplace, may be avoided by a close regard of its characteristic clinical features, which will now be considered.

The innocent murmur is not a significant or noteworthy murmur; some length of clinical experience may be necessary to judge its peculiar intensity, but it is enough to remember that it is neither a loud nor a long murmur. There is one notable exception to this rule—namely, that when the murmur is *late* in systole and placed as near to the second heart sound as the first, it can be loud (and usually it is loud), and yet it is an innocent murmur: the importance of recognizing this fact lies in the common incidence of the auscultatory finding.

Most organic murmurs are better heard with the patient in the reclining posture, and this may sometimes be true of the innocent murmur; but when the murmur is decidedly louder in the upright posture it is the innocent kind.

In instances in which a trivial systolic mitral murmur becomes louder in the reclining posture, and in which a murmur develops at the base of the heart and particularly in the pulmonary area, the innocent nature of the murmur can be presumed.

Any murmur or heart sound is loudest at the end of expiration, but if during the inspiratory phase a murmur disappears it belongs to the innocent type.

A systolic murmur attendant on organic heart disease invariably gains in intensity with tachycardia, but the innocent murmur often weakens as the heart rate increases.

Naturally when a murmur has been judged to be the innocent kind no heart disease can be made out by further examination, including cardioscopy. Recourse to this test should be had whenever the identity of the murmur remains in doubt from clinical examination alone. At all events when the test is readily available it should be used to endorse the clinical impression which has been gained. This test, reliable as it obviously is, should not, however, be allowed to displace our trust in these simple auscultatory signs, which seldom miscarry in the evaluation of this murmur.

Nothing is gained by debating the mechanism of the innocent mitral systolic murmur; for in such a debate, which cannot muster facts and must naturally resort to theories and fancies, lies the danger of allowing this murmur to continue to mystify clinicians. Let us instead adhere to actual clinical findings, and allot to them their proper values in terms of structural changes in the heart as told later by cardioscopy or even necropsy.

The Murmur of "Mitral Incompetence"

As often as we diagnose mitral incompetence, can we prove that the blood regurgitates from the left ventricle into the left auricle during systole? What is the evidence of mitral incompetence when the heart is examined at cardioscopy or necropsy? Certainly when the analogy between this condition and the standard effects of other cardiac abnormalities is considered, enlargement of the left auricle should be a constant finding; but this sign is absent unless some cause other than mitral incompetence is operating, notably mitral stenosis and, less often, prolonged hypertension. The diagnosis of aortic incompetence has a significant meaning because precise signs (clinical, radiological, and pathological) are identified with the lesion. We have no such clear impression of mitral incompetence. It is time, then, to be rid of the term; if preserved it will continue to frustrate the precise diagnosis of heart disease. Instead, when a systolic murmur in the mitral area has not been identified with the irrelevant mitral murmurs in the first group, or the innocent murmur in the second, it should be regarded as standing for mitral stenosis, aortic stenosis, aortic incompetence, or prolonged hypertension; and, less frequently, cardiac aneurysm and cardiac enlargement in heart-block.

The murmur is moderately loud, and is usually best heard with the patient in the reclining posture, although assuming the upright position does not annul it. It is sometimes soft, but as a rule it is roughish or even rough. It is unaffected by respiration, and may become louder when tachycardia is induced.

These clinical states which are common causes of a mitral systolic murmur need only be discussed briefly.

Mitral Stenosis.—Whenever a systolic murmur in the mitral area is considered to indicate mitral disease the term "mitral stenosis" should be used in the diagnosis and not "mitral incompetence." This is in keeping with changes in the heart, for both at cardioscopy and at necropsy the findings are those resulting from the stenotic effect.

It is necessary to assemble other clinical signs to confirm the presence of mitral stenosis in addition to the systolic murmur, which is moderately loud and is best heard in the reclining position, with the patient turning on to the left side after tachycardia has been induced by exercise. A past history of acute rheumatism is small supporting evidence, since not all cases of acute rheumatism develop mitral stenosis and not all cases of mitral stenosis provide a past history of the infection. A thrill in the mitral area is strong evidence of mitral stenosis. A diastolic murmur (always rough) in the position of the third heart sound (mid-diastolic) also stands for mitral stenosis, although it is not an early sign. In fact, when the lesion is young the clinical deduction that a systolic murmur in the mitral area indicates the presence of mitral stenosis may be drawn from finding a significant systolic mitral murmur in the absence of aortic valvular disease, hypertension, and conspicuous cardiac enlargement: cardioscopy should come into regular use here to confirm a well-considered clinical opinion.

In *aortic stenosis* it is unusual to find the mitral area without a systolic murmur. As a rule this murmur is less loud than in the aortic area, but it can be as loud; should it be much louder in the mitral area the added diagnosis of mitral stenosis should be entertained.

A mitral systolic murmur is present in all but early cases of *aortic incompetence*. It should become the custom to expect this murmur in both aortic stenosis and aortic incompetence when there is no need to seek any other explanation of the auscultatory sign.

A systolic mitral murmur is hardly ever absent in *prolonged hypertension* when considerable cardiac enlargement is also a common association. It is not denied that in cases of gross left ventricular hypertrophy some degree of mitral regurgitation takes place; but the view held here is that this diagnosis alone, devoid as it is of a radiological or pathological pattern, does not usefully add to a precise diagnosis of the cause—namely, hypertension.

Cardiac aneurysm following cardiac infarction, and the enlarged heart associated with some instances of *heart-block*, are two rarer causes of a systolic murmur in the mitral area, but the characteristic ancillary data will readily explain the significance of the auscultatory sign.

Conclusion

So long as auscultatory signs in the heart remain unidentified with characteristic features, so long will they miscarry in diagnosis and frustrate the proper management of patients presenting them. The time is overdue to unify our views on the commonest of them all, the systolic murmur in the mitral area.

TREATMENT OF CHRONIC ULCERATIVE COLITIS BY PNEUMOPERITONEUM

BY

H. NEUMANN, M.D.

Medical Officer, Government Hospital, Apia, British Western Samoa

In many cases of chronic ulcerative colitis conservative medical treatment is ineffective. A considerable number of drugs are usually tried, and patients are kept in bed for months under strict diet and daily irrigations. Some recover after prolonged treatment, others find temporary relief; but there are always cases which seem intractable. Sufferers from this not rare disease frequently belong to the intelligentsia between the ages of 20 and 30, and as even milder forms with 8 or 10 daily bowel motions make them unsociable and unfit for work, drastic therapeutic methods have been employed.

Many writers are in favour of extensive colon resection, and H. W. Cave of New York proposes subtotal colectomy as the method of choice. He believes that the percentage of lasting cures is so small that colectomy is a measure of necessity. On the contrary, we have obtained excellent results in chronic, apparently intractable, cases with a far less drastic and dangerous method—the establishment of a therapeutic pneumoperitoneum and its maintenance over several months. With this measure the patient is not confined to bed except for the first few days, and his sojourn at the hospital can be limited to a short time. Indications for pneumoperitoneum were made on clinical grounds—perchronicity, diarrhoea, pus, mucus, blood in stools, intractability—and little weight was put on bacteriological findings, as various organisms caused clinically indistinguishable forms.

Technique of Pneumoperitoneum

The technique is simple, and can be carried out by any practitioner. The therapeutic pneumoperitoneum may be installed with any model of the usual pneumothorax apparatus and with the same needles as are used for the pneumothorax—the most suitable being fairly thin ones with closed, wedge-shaped, not very pointed end and lateral opening, and a diameter of about 1/25 in. or less. Using such needles, local anaesthesia is not required. The best place to puncture is about an inch to the left of and below the umbilicus. After painting the skin with iodine, and examining the needle for free passage of air, the skin is well stretched between two fingers to give resistance to the needle, which, still in connexion with the manometer of the pneumothorax apparatus, is pushed through skin and abdominal wall. After short practice it is not difficult to distinguish, from the resistance to the needle, the layers of the abdominal wall, and particularly the piercing of the peritoneum. This moment is rather more painful than when the pleura is pierced, but with sufficiently thin needles I have never found it necessary to use novocain, which would make it more difficult to distinguish the abdominal strata. It also seems that the patient soon becomes accustomed to the pain of the piercing of the peritoneum, and after several refillings it is felt but little.

It is more important than with pneumothorax to feel the strata at the progress of the needle, as of course the manometer gives no indication whether the needle has passed the peritoneum. The danger of piercing the bowels seems very remote: the smooth intestines escape the needle if they are not too tympanitic and if the needle is not too pointed. Also, with the finer needle there would be no danger if the bowels were pierced.

Before passing air through the needle it is advisable to test with a stylet whether blood or any liquid is present. The amount of gas introduced averages 500 c.cm.—oxygen or air being used. The reading at the manometer is round about zero, rising slightly after the filling of each fraction and dropping again quickly, eventually remaining at 2 or 3 cm. H_2O. Sometimes slight oscillations corresponding to the respiration are noticeable. If the needle has not yet reached the peritoneal cavity the manometric pressure of course rises rapidly, even after introducing the smallest amount of gas. The manometer serves in this sense as a control.

Another control is the reduction and the disappearance of the dull liver sound on percussion. During or soon after the filling, the patient usually complains about the sudden appearance of pain in one or both shoulders; this is of so regular occurrence that it is advisable to tell the patient beforehand about it and to reassure him. The appearance of this phenomenon and the projection of pain to the shoulder region are obviously due to the phrenic nerve, and can also be used as a control; the effectiveness of the filling can further be checked by means of radiographs.

Refilling can be done once or twice weekly; when pure oxygen is used the intervals are 3 or 4 days because of more rapid absorption. When air is used the intervals are from 6 to 8 days. Because of its calming effect oxygen is preferable for the first fillings for cases with major abdominal discomfort and frequent colics, and for cases with a higher grade of secondary anaemia and dyspnoea. The number of fillings required varies greatly, and it may be necessary to continue treatment for three months or more.

Results

Of the 7 cases in the series only one was treated for more than 3 months.

Case 1.—A woman aged 28 had been suffering for 3 years from severe diarrhoea. She had from 15 to 25 bowel motions daily—in better periods and under the influence of opium 10 to 12 motions—always with an admixture of mucus and blood, occasionally pus. Loss of weight was 46 lb. in 3 years. During three months' treatment with pneumoperitoneum the number of bowel motions was steadily reduced and she regained 17 lb. Her general condition improved, and finally the stool was free from mucus and blood. The diagnosis of ulcerative colitis had been confirmed by sigmoidoscopy. Investigation after one year showed that she was free from complaints and had further gained in weight.

In one case only two fillings were required. Particulars of this case are as follows:

Case 2.—A man, part Polynesian, aged 42, had been suffering from symptoms of chronic colitis for several years. His loss of weight was over 30 lb. and there was incapacity for work and general debility. After pneumoperitoneum and one refilling he felt well. No sigmoidoscopy had been carried out; the presence of a tumour in the colon suggested by severe secondary anaemia had been excluded by radiological examination. Re-examination after 7 months showed that the patient had gained 14 lb. He was still feeling well and was able to work.

In some cases a moderate amount of peritoneal effusion developed; this liquid was sooner or later reabsorbed spontaneously. In such cases it is advisable to give 10 c.cm. of calcium chloride intravenously 3 times weekly. It appeared also that patients who developed temporary ascites responded more quickly to treatment.

Summary

The therapeutic action of pneumoperitoneum is probably due partly to activating the visceral peritoneum and "tuning it to a higher pitch" by the setting up of a permanent bland irritation to the vast peritoneal surface, and partly to mechanical action and indirect influence on the autonomic nervous system.

Pneumoperitoneum may be described as a simple and effective therapeutic procedure in apparently intractable cases of chronic ulcerative colitis. It is easily performed, and is free enough from danger for it to be introduced, and for refillings to be made, by any practitioner, even without the facilities of a clinic or a hospital.

SOME OBSERVATIONS ON BILIARY PAIN

BY

ALASTAIR A. DOUGLAS, M.D., F.R.C.S.Ed.

The recent article by Mr. F. R. Brown (1942) in the *Journal* has prompted me to record some clinical observations on biliary pain. The classical "pain" of what is loosely termed biliary colic is really, of course, a pain complex, which has been split into components and explained by Morley (1931). My hope is only to add a very little to what he and others have already said.

Components of the Biliary Pain Complex

I think that in a fully developed case five components of the complex can be recognized, though more commonly only two or three are met with.

1. In most cases of biliary colic the pain is first felt by the patient as a violent if dull ache in the central epigastrium, coming in waves. Like other visceral pains it is absorbing, so that the sufferer for the time being is as if paralysed, and almost identified with his own pain. If he can divert his attention from it for long enough he will pass his hand from side to side across his epigastrium, from one costal margin to the other, to indicate its position, which he still cannot describe with any accuracy. I should be inclined in the case of biliary colic to convert the vertical oval in Fig. 5 of Brown's article to a horizontal one (Fig. 1). In some cases, more particularly when the attack is short and infection slight or absent (as evidenced by freedom from pyrexia and leucocytosis), this component is the only one felt, and there may be no tenderness over the gall-bladder. I have also been able to observe one of the cases in which an idiosyncrasy to morphine has developed after cholecystectomy, and which Smyth (1941) quotes Walters (1938) as ascribing to spasm of the sphincter of Oddi. In this case the pain provoked by morphine was

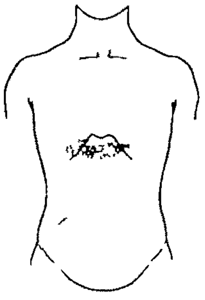

FIG I

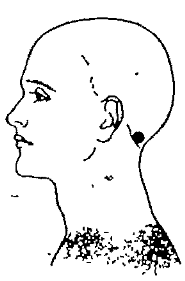

FIG 2

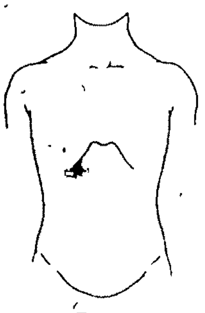

FIG 3

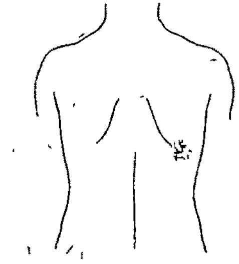

FIG 4

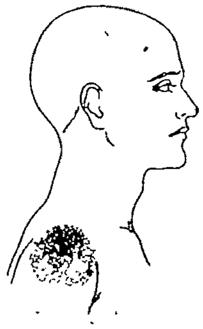

FIG 5

of the nature described above—a severe but not definitely localized transverse pain in the epigastrium.

2. The second component is certainly inconstant, but I am surprised that I cannot find any direct reference to it in the works I have consulted. Moynihan (1905) mentions that pain (during the acute colicky phase) may be felt in the chest, and Cope (1925) recorded pain in the back of the neck in a patient found to have a stone in the common bile duct. He also quotes Reynolds's *System of Medicine* as mentioning pain radiating to the clavicles; but I cannot find a suggestion that there is a second type of visceral pain occurring in biliary disorders. I feel satisfied that there is. It is a severe dull ache, said by the patient to be in the neck—most severe in the back of the neck, but also radiating in front to the clavicular regions. It is symmetrical, and one patient described it as "like a necklace of pain" (Fig. 2). It may be so severe as to overshadow the epigastric pain, which is also present. It occurs early in the attack, accompanying the first component.

3. As is well known, rather later in the attack a third component appears—pain in the right side below the costal margin, and accurately located by the patient. At the same time local tenderness develops, elicited by very light tapping with the tip of a finger (Fig. 3).

4. The fourth component often arises about the same time, is met with in severe attacks, and is said by the patient to "go through to the back"—to the region of the angle of the right scapula. In character it is similar to component 3, and different from the paralysing waves of pain of components 1 and 2 (Fig. 4).

5. According to Morley (1931) shoulder-tip pain is present in only 5% of cases. In my experience it is not remarked on by the patient during the colic, though it may be present; but the information can at times be elicited from him that it preceded or followed the attack. It resembles components 3 and 4 in nature, and is often thought by the patient to be an intercurrent rheumatic pain (Fig. 5).

Explanation of the Various "Pains"

The explanation is an interesting exercise in the light of current theories. According to Brown's theory of primary position, the first component is related to the derivation of elements of the bile passages from an outgrowth of the foregut caudal to the stomach, and thus innervated by the 8th and 9th thoracic nerves, which is the segmental distribution of the pain. I submit that there are also good embryological grounds for an explanation of the situation of the second component, which to my mind is also a visceral pain. Mesodermal elements of the bile passages derive from the septum transversum, like the central part of the diaphragm, and, also like it, are innervated from the primary positional nerves C3, 4, and 5. The visceral pain connected with these elements would, according to Brown's hypothesis, be felt in the region of the neck supplied by these nerves, and this accords exactly with my observations.

It seems hardly necessary to repeat Morley's explanation of the third component. The inflamed or congested peritoneal coat of the gall-bladder irritates an area of the parietal peritoneum and sets up "peritoneo-cutaneous radiation" from the nerves of the anterior parietal peritoneum to the more superficial branches. I would add two observations in support of this view. First, in cases in which the inflammation of the gall-bladder has practically subsided pain can be reproduced by the patient's actively protruding and retracting the abdominal wall for a few seconds, or it may be provoked by walking—both of which movements can be taken to increase friction between the gall-bladder wall and the anterior parietal peritoneum. Furthermore, in one case of chronic cholecystitis, later confirmed by operation, the localized pain below the right costal margin came on before the main meal of the day, was aggravated by walking, and was at once relieved by taking the meal. The clinico-pathological interpretation is as follows. When the inflamed gall-bladder was distended with bile it was in contact with the anterior parietal peritoneum, and pain was set up which was relieved by the shrinking of the gall-bladder and its retraction after the meal.

The fourth component is explained in a similar way by cutaneous radiation occurring from the posterior parietal peritoneum, which later in the attack becomes inflamed. That considerable disturbance does take place in this region is shown by the frequent occurrence of crepitations, and by other evidence of congestion at the base of the right lung.

Morley (1931, p. 28) remarks that while gall-stones do not at all commonly give rise to shoulder-tip pain they are responsible for almost the only reference to it in the surgical textbooks. He adds: "The reason of this is to be found in the confusion that has arisen between the 'shoulder pain' or pain radiating to the angle of the right scapula, which is an almost constant feature of biliary colic, and true shoulder-tip pain due to phrenic stimulation."

I suggest that the pain in the back of the neck and clavicular regions, which I have described as the second component and which has all the features of visceral pain, is an equally likely cause of the confusion. Shoulder-tip pain properly so called does of course arise in biliary disease. Hurst (1934), for example, mentions it as occurring in hepatitis or "bilious attacks." A very interesting light on this problem was shed by a case I observed a few months ago.

The patient, a healthy man aged 36, had a severe attack of epidemic catarrhal jaundice, the source of infection being known, and he also in his turn infected a third person. On the tenth day of his illness, the jaundice being very deep, I casually asked him if he had shoulder-tip pain, and he agreed that he had. On local examination, a striking appearance of the right shoulder presented itself. There was an area of erythema, slightly raised above the surface and dotted with small closely set papules. It was almost circular in outline, and was five inches in diameter, with its centre over the tip of the acromion process (Fig. 5). It corresponded exactly with the area outlined in an illustration in Morley's book (p. 37) showing the area of pain and hyperalgesia in a case of traumatic laceration of the spleen.

It seems justifiable to assume that in the case described a corresponding area of stimulation on the right side was the cause of the pain and its accompanying phenomena—namely, the contact of the inflamed surface of the liver with the central part of the diaphragm. This leads me to the conjecture that shoulder-tip pain in biliary disease is commonly due to concomitant hepatitis. The cutaneous eruption faded in a few days, and I was unable to elicit any marked hyperalgesia over it. Whatever the explanation of the process which had given rise to it, there can be no doubt as to its objectivity, and it seems to me to give support to Morley's views.

It is to be noted that the five components may follow one another in varying order. Thus in one case the first complaint was of pain below the right costal margin of several weeks' duration (third component), and probably attributable to commencing metastatic infection of the gall-bladder. This was followed by slight jaundice and shoulder-tip pain (fifth component), presumably due to hepatitis; and then a few days later by the first and second components, which coincided with attempts by the gall-bladder to expel solid or semi-solid matter which had precipitated by this time.

Summary

The biliary pain complex is split up into five components and explained in the light of current theories. Special reference is made to a variety of visceral pain arising in the bile passages which is not well recognized. Reference is also made to a case of epidemic jaundice in which shoulder-tip pain was associated with a cutaneous eruption.

I am indebted to Mrs. J. M. D. Young for the figures

The name of the Federal Council of Australian Aerial Medical Services has recently been changed to "Flying Doctor Service." The service has six bases in remote parts of Australia, which keep in touch with about 250 outposts by two-way radio. The cost of upkeep is £21,000, partly financed by the Federal and State Governments and partly by private contributions. The service is at present suffering from shortage of staff because many doctors, pilots, and wireless operators have enlisted.

Medical Memoranda

A Case of Adenocarcinoma of Jejunum

Malignant tumours of the jejunum are not common. Stein (1937) finds that they comprise only 1.3% of all malignant bowel tumours—including the stomach—over a five-year period. A study of 108 cases of malignancy in the small intestine by Chas. W. Mayo (1940) showed that the average age of patients was 52 years. These cases formed 0.7% of all malignant bowel tumours over a period of 33 years. He finds that only 42.4% are resectable and the mortality is 30%. The case here recorded is of interest because of the age of the patient, the lack of bowel symptoms, and the size of the tumour.

CASE RECORD

An Army patient aged 29 was admitted to a medical ward in this hospital in Jan., 1942. He gave a history of pain in the back. It was of an aching character, almost always present, made worse by marching, and relieved by taking a deep breath. The pain had been present for five or six weeks. He had been treated elsewhere four weeks before admission, and had been given tablets, which afforded relief. There was no history of cough or night sweats. He did not know if he had lost weight, but realized he had lost colour. He had vomited twice, but there were no other abdominal symptoms whatever. A mass was discovered in the abdomen, and I was asked to see him on Jan. 20.

Examination showed a very pale man with a slight cyanotic tinge to his mucous membranes. There was a mass to the left of the umbilicus; it was as big as a grapefruit, hard, somewhat irregular, not tender, and could be pushed up until the upper edge was hidden behind the left costal margin. The essentials of the blood picture were: R.B.C. 2,100,000; haemoglobin 45%. I advised transfusion and laparotomy, the provisional diagnosis being malignancy of colon or greater curvature of stomach. A transfusion of 750 c.cm. of blood was given that afternoon (Jan. 20), and the man was transferred to the surgical unit.

Next day a second drip transfusion was given, during operation, which was carried out under gas, oxygen, and ether. A left paramedian incision disclosed a large tumour of the upper jejunum, involving the mesentery to a much greater extent than the bowel. The proximal edge of the tumour was only a few inches from the duodeno-jejunal junction. The mesenteric involvement demanded a wide bowel resection (30 in.): to do this the duodeno-jejunal flexure and part of the third portion of the duodenum were mobilized. Resection and side-to-side anastomosis were performed. On Jan. 23 the red cells numbered 4,600,000, with haemoglobin 80%. The patient was very well despite a productive cough. On Feb. 6 he was up and about.

The pathological report reads: "Sections show an adenocarcinoma, apparently primary in the jejunum, invading deeply into the mesenteric tissues and local lymph glands."

I am indebted to the Department of Health for Scotland for permission to publish this case.

A. H. SANGSTER, F.R.C.S.Ed. & Eng.,
Surgeon in Charge of Surgical Unit in an
E M S. Hospital in Scotland.

Gynaecomastia produced by Desoxycorticosterone Acetate (Doca)

Enlargement of the male breasts during treatment of Addison's disease with "doca" seems to be unrecorded, but it occurred recently in a patient under my care.

A diabetic man of 32, who had lived on insulin for 20 years, developed typical Addison's disease in the autumn of 1941 and a severe crisis in 1942, from which he was rescued by large doses of eschatin salt, etc. Later an unsuccessful attempt was made to substitute doca, and large doses were given. After 15 mg. daily for a week the breasts were perceptibly enlarged, and after 20 mg. for another week much more so. They began to subside 3 days after stopping doca and resuming eschatin, but did not become normal until 2 weeks later. *Pari passu* with this enlargement the patient experienced intense libido, including erections, in spite of extreme debility and the feminine breast manifestations. The latter consisted in considerable general glandular enlargement and slight tenderness, without nipple changes or any sign of lactation. I did not try to reproduce the effect by another course of doca as it caused general oedema. The maintenance dose of cortical extract is 30 c.cm eschatin a day.

Doca has been shown to cause gynaecomastia in mice (*Proc. Soc. exp. Biol.*, N.Y., 1939, **41**, 389), and eschatin (6 c.cm. daily) in one male patient with Addison's disease (*J. Amer. med. Ass.*. 1938, **111**, 412). In my case, however, eschatin alone had no such effect, for when doca was stopped the mammary enlargement disappeared in spite of continuous large doses of eschatin.

Reviews

ACUTE HEAD INJURIES

Acute Injuries of the Head: Their Diagnosis, Treatment, Complications, and Sequels. By G. F. Rowbotham, B.Sc., F.R.C.S. With a foreword by Norman M. Dott, M B., F R C.S.Ed. (Pp. 288; illustrated. 25s., plus 7d. postage) Edinburgh: E. and S. Livingstone. 1942.

This book should rank high among monographs on head injury. It is written in a direct and practical way, primarily for those responsible for the early treatment of head injuries—that is to say, for surgeons and general practitioners who have had no special training in neurology or neurosurgery; and thus, in an attempt to supply the necessary background, the author has included much information of a general kind on such subjects as cerebral localization, radiographic methods, and neurosurgical technique. The main sections of the book deal with pathology, diagnosis, and treatment of head injuries, but there are also chapters on the dynamics and on the sequels of head injury. Mr. Rowbotham was well qualified to write this book: first with Prof. Geoffrey Jefferson, to whom the book is appropriately dedicated, and then in his own clinic at Newcastle, he has personally dealt with over 1,000 cases of head injury. That his experience has been comprehensive may be judged from the fact that he reports observations on 200 patients unconscious after head injury, and 500 cases of the post-concussional syndrome, as well as on gunshot wounds and air-raid casualties.

Of the need for a book of this kind at the present time there can be no possible doubt. From the figures which Mr. Rowbotham gives it is not improbable that head injuries in this country amount to well over 100,000 a year. The majority of these are, and must continue to be, treated from first to last by general practitioners and general surgeons, and, as the war has revealed, the treatment provided has been not infrequently at fault, especially the manner of repair of open wounds and the management of convalescence. This book provides sound and detailed instruction in the diagnosis and treatment of acute head injury, with admirable hints on the nursing problems; and the picture is not obscured, as so often it was in the past, by attempts on the part of the writer to link the symptoms with hypothetical pathological events. The instructions for treating shock, and examining for injuries in other parts of the body before attempting to treat the head wound, are just what the surgeon dealing with accidents requires. For severe head injuries, with certain reservations, the author favours moderate dehydration, though the figures he quotes to support active surgical measures—such as dehydration, spinal drainage, or decompression—are without statistical significance. Apart from repair of head wounds, operation is only required in a very small proportion of the cases, and the detailed description of the operation of subtemporal decompression seems rather unnecessary in view of the fact that Mr. Rowbotham performed it only 5 times in his 1,000 acute cases. It is also open to question whether the general surgeon is qualified or equipped to perform the operation.

In the section devoted to the sequels of head injury there is a comprehensive and sympathetic account of the factors which interfere with the patient's adjustment to his accident. The author has very definite ideas about the causes of post-traumatic headache and dizziness: he believes that they are mostly organic in origin, but he recognizes also that they are subject to psychological influences, and that in each case there is an interplay of the functional and the organic. There is much useful information on the compensation aspect of head injuries, but the reader is perhaps left with an unduly gloomy view of the late results of head injury. There is too little indication of the fact that by far the most common sequel of head injury is early return to work and, in spite of occasional headaches, a fairly rapid recovery of previous working capacity. Failure to recognize this fact handicaps the doctor considerably in the after-treatment of head injuries.

The subject of head injuries is a complicated one, and Mr. Rowbotham has not sought to over-simplify. He has produced a well-printed and well-illustrated book which will act as a guide and stimulus to all who deal with the immediate and remote effects of head injury. In the words of Mr. Norman Dott, who writes a foreword, Mr. Rowbotham shows "a wide grasp of the problems raised by brain injury—neurological, psychiatric, and social, as well as surgical."

MEDICAL ASPECTS OF WORKMEN'S COMPENSATION

Workmen's Compensation and the Physician. A Manual for the Use of General Practitioners and Insurance Carriers. By Henry H. Jordan, M.D. With a Discussion of Traumatic Neuroses by Paul H. Hoch, M.D. (Pp 180. 16s.) London, New York, and Toronto: Oxford University Press. 1941.

No volume similar to this has yet been written in the United Kingdom, probably because the medical profession have not hitherto regarded workmen's compensation as the important branch of medicine which it is. Dr. Jordan has spent twenty years at this work, partly in charge of a clinic for injured workmen and partly as a medical referee, and has drawn upon an experience of over 30,000 compensation cases. He felt the need in the United States for a small book which would tell the general practitioner and the insurance carrier the basic principles of the treatment of "compensable injuries." It stresses the peculiar problems which arise when a workman, as distinct from an ordinary patient, suffers from an injury. The author therefore deals, concisely but most usefully, with such questions as causal relation between injury and disability, the aggravation of pre-existing disease, expert opinion, and the evaluation of disability. After some sound practical advice on the first examination of the injured employee, he discusses treatment in the consulting room and the home, admission to hospital, and treatment by specialists. He devotes a special section to *x*-ray examination, the interpretation of findings and expert opinion, common causes of diagnostic errors, and the postulates which should protect the doctor against them. Other chapters deal with physical therapy and orthopaedic appliances, and Dr. Hoch's section on traumatic neuroses is a useful introduction to this difficult subject.

The book is short, and does not purport to be more than a condensed guide. As such it may be warmly recommended to every practitioner who is called upon to act in these cases. The reader may, however, hope that Dr. Jordan will some day write a far fuller treatise on the subjects which he here outlines so ably.

A MIDWIFERY TEXTBOOK

Midwifery. By Ten Teachers. Under the direction of Clifford White, M.D., M.S. Edited by Sir Comyns Berkeley, Clifford White, and William Gilliatt. Seventh edition. (Pp. 562; illustrated. 18s.) London: Edward Arnold. 1942.

Time and the war have brought changes to the distinguished list of contributors to this excellent little textbook. One of the original ten, Dr. Barris, has been replaced by Mr. John Beattie, and Major (now Colonel) Frank Cook has been temporarily replaced on the editorial staff by Mr. Gilliatt. The book has been thoroughly revised and greatly improved, but reduced in size. From cover to cover it is full of concise and sound obstetrical teaching. Emphasis is placed on the value of Caesarean section in the treatment of placenta praevia, but the student is reminded that good results can be obtained only if adequate facilities and skilled assistance are available. In discussing abnormal uterine action the authors now use the phrase "tonic retraction" in place of "tonic contraction"—a useful change, but one that will be disputed by some teachers. The suggestion that 5 to 10 units of pitocin should be injected into the uterus before the delivery of the child in lower-segment Caesarean section has little to commend it: the practice can make an easy operation difficult and even result in foetal death. The new edition will maintain the popularity of its predecessor.

Notes on Books

For years past Dr. T. WILSON PARRY has pleased his friends by sending them at Christmas a copy of his latest verse, usually in sonnet form. He has now published some of these, with additional pieces, in a pamphlet, *The Spirit of "This England"* (The Mitre Press, Mitre Street, E.C.3), which well represents his feeling for beauty and for metre.

The appearance of a third edition of Dr. BRADFORD HILL'S *Principles of Medical Statistics* (published by the Lancet Limited at 7s. 6d.) is evidence that, even in wartime, scientific education continues. The present does not differ substantially from the second edition, and we need not repeat in detail what was said in an earlier notice. We congratulate both Dr. Hill and his readers on a notable success.

Science and World Order is the title of a 9d. Penguin Special in which J. G. Crowther, O. J. R. Howarth, and D. P. Riley use as their raw material the communications made by a number of speakers at the conference on that subject held under the auspices of the British Association in September, 1941. The text has been prepared with the authority of the Council of the Association, and it includes chapters on science and government, world resources, health and food, post-war relief, and science and world planning. The chapter on health and food quotes in particular from Sir John Orr's address to the conference.

The *Fifth Supplement to the British Pharmaceutical Codex, 1934,* contains a number of additions and amendments to monographs and a cumulative index to the five Supplements. The amendments include changes in the formulae for preparations in which quinine is not regarded as an essential constituent, in accordance with recommendations of the Therapeutic Requirements Committee of the Medical Research Council. This Supplement like its predecessors, is published by the Pharmaceutical Press, for the Council of the Pharmaceutical Society of Great Britain, and the price is 2s. 6d.

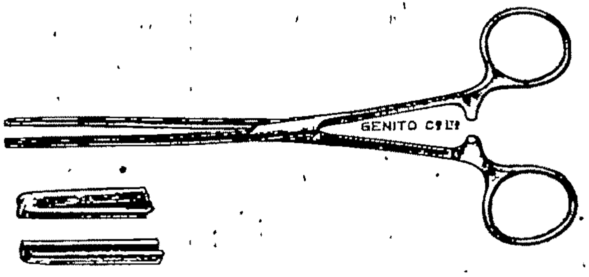
Preparations and Appliances

CLAMPS FOR ABDOMINAL SURGERY

Mr. D. LANG STEVENSON, F.R.C.S., surgeon to the Oldchurch County Hospital, writes:

As I have found a pair of small clamps made for me by Mr. Schranz of the Genito-Urinary Manufacturing Company to be of considerable value in gastro-intestinal surgery, a brief description of their use may be of interest to other surgeons.

The clamp, which is here illustrated, is 8 in. long with a blade length of 3½ in. The closed blades on the flat taper from 1/4 in. to 1/8 in. at the tips, whilst on the opposite aspect they have a uniform width of about 1/8 in.



The clamp combines to an unusual degree the advantages of lightness, slenderness, and strength. Gut is held securely in the bite of the narrow blades by means of a single deep longitudinal groove in one of them and a corresponding ridge on the other. In these respects this clamp excels any other that I have seen designed for the same purpose. With the extreme cut edge of stomach or intestine in the control of the clamp a clean and bloodless closure or anastomosis is greatly facilitated.

Some of the numerous instances in which these instruments have proved their usefulness in simplifying and perfecting technical procedures in gastro-intestinal surgery are closure of the duodenal stump in gastrectomy; aseptic anastomosis after resection of bowel, or for the accomplishment of cholecystenterostomy; and closure of colostomies or intestinal fistulae.

SULPHANILAMIDE FOR LOCAL APPLICATION

Attention has been drawn recently to the risk of anaerobic infection from locally applied sulphonamides. To obviate this risk a sterile preparation of sulphanilamide is now issued by Burroughs Wellcome & Co. as "Wellcome" brand sterilized sulphanilamide compound, a free-flowing mobile powder consisting of finely divided sulphanilamide with 5% of zinc oxide; the latter is to facilitate complete sterilization without aggregation of the sulphanilamide particles, and also to retard absorption of the compound from the site of application and thus prolong the local chemotherapeutic action. The product is issued in bottles of 15 grammes.

BRITISH STANDARD HAEMOGLOBINOMETER

A new British Standard specification for haemoglobinometers (Haldane type), No. 1079/1942, has been published, and copies are obtainable from the British Standards Institution, Publications Department, 28, Victoria Street, London, S.W.1, price 2s. (2s. 3d. post free).

Hitherto there have been inconsistencies between colour tubes. Further, in the Haldane method as practised an inconvenience is that neither colour tubes nor graduated tubes are fully interchangeable but have to be matched up so that colour tubes are only used with graduated tubes of the same internal diameter. The new standard defines the colour tubes on the trichromatic scheme adopted by the International Commission on Illumination in 1931. This provides a permanent definition of the tubes and makes possible the rapid verification of any individual tube. Further, all colour tubes complying with the specification are interchangeable with each other There are provisions which ensure the interchangeability of the graduated tubes, so that any graduated tube complying with the specification may be used in conjunction with any standard colour tube.

There is evidence that the new standard colour tubes are in close agreement with Haldane's original standard; the use of the new standard does not call for any change in technique in testing a sample of blood; and the manufacture of tubes to comply with the specification does not complicate, but in some ways simplifies, the method of production Hence with the minimum departure from current practice the new standard will enable different workers to obtain results on a more strictly comparable basis than has hitherto been possible.

The National Physical Laboratory is prepared to accept haemoglobinometer colour tubes and graduated tubes for examination for conformity with the British Standard specification. Besides examining tubes definitely made to comply with the specification, the N.P.L. will accept from users tubes which have already been employed in the examination of blood samples and report how far they depart from the new standard. Full particulars of the tests and the fees charged may be had from the Director, National Physical Laboratory, Teddington, Middlesex

CANCER RESEARCH IN SOUTH AMERICA

A detailed account of the activities of the Institute of Experimental Medicine (for the study and treatment of cancer), Buenos Aires, is given in a recently published volume[1] of 921 pages. The *Boletin* is issued periodically and is devoted primarily to the work carried out under the direction of Prof. Angel H. Roffo, whose contributions to the study of the cancer problem are widely known. It includes several original papers and notes by Prof. Roffo and his colleagues, and also contributions from other S. American workers, and gives an impressive picture of the work being developed in this field in the S. American countries, particularly Argentina. That the clinical and social aspects of cancer are not neglected is clearly demonstrated by the statistics and other data in this volume.

Prof. Roffo's own paper on "experimental gastric carcinoma induced by ingestion of fuel-oil distillates" is a suggestive contribution to the theory that the products of combustion of petrol may be a factor in the production of cancer in town-dwellers. The paper is illustrated by 19 photographs and 44 photomicrographs, all of which are excellently reproduced. Two notes by Prof. Roffo's son—"CO in Patients with Carcinomata" and "Induced Radio-activity"—are followed by another work on maxillary tumours by Prof. Roffo and Dr. del Giudice, and an account is given of the surgical treatment of carcinoma of the penis, based on 350 cases admitted to the Institute from 1936 to 1940. Dr. A. Carini from São Paulo (Brazil) contributes a note on a spontaneous carcinoma in the skin of a rabbit with metastasis in the lungs, and Drs. G. Gonzalez and J. Boggino from the Faculty of Medicine of Asunción (Paraguay) describe a case of plasmocytoma or plasmocytosarcoma of the ribs, diagnosed by biopsy. Several other interesting contributions by Paraguayan doctors are also included. All papers are well illustrated. Rather more than 100 pages at the end of the volume are devoted to the affairs of the Institute, in which 1,780 patients were seen during the second quarter of 1941, while during the same period 237 surgical operations were performed and no fewer than 11,760 treatments with radiation were given. Books, reports, and papers received from several countries by the Institute are also briefly reviewed, and include the *Annual Reports* of the British Empire Cancer Campaign and the Imperial Cancer Research Fund.

OPHTHALMOLOGY AND SOCIOLOGY

In a suggestive paper[1] Prof. Arnold Loewenstein of Prague, now working at the Tennent Institute of Ophthalmology of Glasgow University, says it is often asked: "how to prevent blindness"; he would rather put the question thus: "how to preserve the eyesight." Everywhere in modern medicine prophylaxis is more highly valued than healing—the path of medical development runs clearly on these lines. Discussing the main causes of blindness, he then suggests means of prevention. It is not easy to prevent hereditary disease or defects. He suggests that districts might have advisory offices for engaged couples, where they could get guidance. He thinks a good film on hereditary diseases might be more interesting than the best detective thriller. With regard to blindness caused by venereal disease the statistics for the whole world prove that this is rapidly decreasing; parental treatment is now well established, and the treatment is distinctly successful. Injuries, especially in industrial countries, are the greatest modern problem; prevention of such damage is not only humane but profitable. Prof. Loewenstein writes: "A great number of the eye injuries in the workshops are due to defective illumination, and at least 15% of all eye injuries are caused by insufficient lighting. One firm installed modern and expensive light fittings and reduced the frequency of the accidents by 7%. Further, industrial efficiency depends upon good vision. Three protective techniques are required: (1) control of toxic materials, gases, dusts, and vapours; (2) use of protective goggles against flying objects and radiant energy; (3) provision of adequate illumination." In his final section he stresses the need for more being done to provide careful teaching of ophthalmology in the medical schools. The nation cannot allow such a training to depend on chance. With a good scheme in operation the nation would soon have a great stock of good eye surgeons to combat blindness and fight the battle for the sight of the rising generation

PATHOLOGICAL SERVICE OF THE L.C.C.

A series of lectures and demonstrations were given on Dec. 2 at the L.C.C. Group Laboratory at Lambeth Hospital to pathologists and consultants of the Royal Canadian Army Medical Corps and the United States Army Medical Corps. Among the visitors were Col. J. A. Macfarlane and Col. L. C. Montgomery, *M.C.*, respectively consulting surgeon and consulting physician to the Canadian Forces, and Lieut.-Col. M. H. Brown, Assistant Director of Hygiene, Canadian Forces; with the American pathologists was Major Ralph Muckenfuss, now in charge of the U.S.A. General Medical Laboratory "A." The visitors were welcomed by Dr. Andrew Topping, deputy medical officer of health, and in the morning short papers were read by Major J. E. McCartney, R.A.M.C., Drs. Robert Cruickshank, W. W. Kay, and R. F. L. Hewlett. The work of the council's hospital service with 35,000 beds for acute and chronic sick and 30,000 for mental diseases, and of its pathological service with its 28 pathologists and assistant pathologists and 105 laboratory technicians, was described. At lunch the visitors were joined by the clerk of the L.C.C., Mr. E. C. H. Salmon, and the medical officer of health, Dr. W. Allen Daley, both of whom welcomed the guests. In the afternoon the council's pathologists and their staffs demonstrated their work, including culture media, leptospiral and salmonella infections, liver function tests, blast and crush injuries, malignant cells in sputum, sternal puncture, estimation of sulphonamides, Neisseria and haemophilus infections, typing of streptococci, diagnosis of intestinal infections and use of desoxycholate medium, diphtheria diagnosis, antistreptolysin titration, etc. The object of the meeting was not only to demonstrate pathological work in Britain to Canadian and American colleagues but to bring the pathologists together and obtain the understanding and co-operation that can only be acquired by personal contact and discussion. From the remarks of the visitors it was evident the meeting was a great success, and it is to be hoped that this is only the first of its kind between British pathologists and those of the Dominions and our Allies.

The Famine Relief Committee (Drayton House, Gordon Street, W.C.1) has issued under the title "Food Conditions in Europe" a leaflet (price 3d.) on the effect of war and blockade on people in German-controlled countries, with a foreword by the Bishop of Chichester. The objects of the committee are to obtain authentic information as to food conditions, and to promote schemes for sending food, vitamins, and medical aid into German-controlled or invaded countries, wherever control is possible in co-operation with existing organizations.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY JANUARY 2 1943

THE CONTROL OF DIPHTHERIA

One of the best-established facts in applied immunology is the usefulness of antitoxic serum in the treatment of diphtheria. The main, if not the only, reason for failure in certain clinical cases is that serum is not given early enough to be effective. This may be because the patient's relatives summon the doctor, too late. Sometimes there is a delay in diagnosis. This is not always the fault of the medical man, for membrane formation in early cases of *gravis* diphtheria may be inconspicuous or absent, leading to a diagnosis of tonsillitis or quinsy. This is particularly unfortunate, because *gravis* and *intermedius* cases sometimes progress rapidly to a fatal end; promptness in giving serum makes all the difference between early recovery and prolonged illness or death.

Modern enzyme-treated sera are of higher unitage per c.cm. and of greater purity than the older unconcentrated and sulphate-precipitated ("concentrated") sera, and larger doses can be given without much risk of serum sickness. There has, however, been no striking improvement in clinical efficacy; indeed, it is sometimes stated that the sera now marketed lack some essential constituent. Although it has been suggested that the newer process of enzyme treatment might eliminate something of value that was formerly retained, the consensus is that these sera are satisfactory.[1] In view of the doubts expressed, however, it is right to ask whether antitoxic serum can be improved and, if so, along what lines. There is evidence that avid sera might be more useful than non-avid, and, although manufacturers may avoid issuing definitely non-avid sera, it is not at present practicable for them to issue sera of uniformly high avidity. Few horses now contain much "natural" antitoxin, and this appears to be correlated with the finding that only a minority produce exceptionally avid antitoxin; these avid sera are blended with many others of average avidity and are then concentrated. If the best sera were excluded from the pool and issued separately their cost would be prohibitive and the level of avidity of all other sera issued commercially would fall.

Is the antigen used for the immunization of horses the best attainable? We know that the content of specific toxin or toxoid in the filtrates commonly injected is higher than it was some years ago, but high potency and specific antigenicity are not necessarily correlated, and competing antigens (broth constituents, etc.) may "crowd out" the required response and affect some quality of the antigen or suppress the formation of some other antibody. Is sufficient attention paid to the "antibacterial" property of serum? Let us admit at the outset that little is known about the use and testing of antibacterial serum, and that even definitions are nebulous, for the word "antibacterial" still provokes discussion among immunologists. The presence of agglutinins and precipitins in a serum might lead some authorities to claim that it is antibacterial, whereas others would restrict the term to serum capable of destroying organisms *in vivo*. Huang[2] of Peking has recently directed attention to an antibacterial property in diphtheria antitoxic serum, which is universally prepared from the Park 8 strain. Organisms of the same serological type as Park 8 disappeared rapidly from the throats of patients during the first two weeks of treatment; organisms of all other types disappeared more slowly. The death rate of patients infected with strains of the same serological type as Park 8, who were of course treated with homologous serum, was not any lower than that of other patients. The author attempts to explain this finding on the basis that practically all the deaths in his series were from laryngeal involvement, and that the antibacterial property of the serum might also be masked by the absence of bacteriaemia, and by the important part the toxin plays in the causation of the disease. There are many other points of interest in Huang's papers which await investigation by other workers. Agglutinins were passively transferred by antitoxic treatment, but these were of the Park 8 serological type, tended to disappear rapidly, and did not interfere with the recognition of agglutinins due to active immunity to the infecting type which developed later. It is not always possible to obtain positive cultures from cases of clinical diphtheria, and Huang records a laryngeal case with only one positive culture during convalescence in which agglutination tests clinched the diagnosis. No agglutinins were found in the acute stage, but the specific agglutinins which appeared during convalescence were of the same type as the organism isolated at this period. Altogether cultures from 268 cases of clinical diphtheria were investigated, among which 8 main serological types of organism were identified. Unlike Okell,[3] Huang could find no evidence for the transformation of virulent into avirulent organisms of the same type in the throat. With the exception of one type, which comprised *gravis* and *intermedius* strains, all of Huang's 8 main types were *mitis*. Thus, *gravis* and *intermedius* types, which are mainly responsible for severe diphtheria in this country, did not come within the scope of Huang's research on antibacterial serum. Be that as it may, we cannot feel confident that this work will have practical clinical application, because it would be necessary to prepare antisera for many serological types of *C. diphtheriae* and have these products available for early use in conjunction with some rapid typing method not yet devised. Again, in the treatment of carriers local chemotherapy should be more generally useful than type-specific serum.

In the safeguarding of contacts Phair and Root[4] recommend simultaneous injection of prophylactic antitoxin and alum-precipitated toxoid. Their work, which was entirely with guinea-pigs, supports the careful studies of Downie and his colleagues[5] on human subjects in this country. Phair[6] also explored the use of an extremely delicate biological method for the further investigation of strains of doubtful virulence. When guinea-pigs were prepared beforehand by a "priming" stimulus, the subcutaneous injection of a minute amount of toxin, toxoid, or culture filtrate of a virulent diphtheria strain led to a definite increase in circulating antitoxin ("secondary stimulus response"). The filtrate of one strain which was regarded as avirulent gave a suggestive increase in titre which may have been due to a minute amount of toxin in the filtrate; in this instance it was impossible to conclude definitely that the strain was really one of low virulence. Another American contribution to the control of diphtheria is the use of chicks in testing for virulence. Frobisher, Parsons, and T'ung[7] injected Plymouth Rock chicks from 7 to 20 days old with 0.5 c.cm. to 1 c.cm. subcutaneous doses of 48-hour broth cultures of strains of *C. diphtheriae* and found excellent agreement (99.7%) with the results previously obtained in rabbits. Perhaps the method might find some application in this country, where the quality of guinea-pigs and other laboratory animals for virulence and other tests is poor; it is unfortunate that there is no national scheme for the large-scale breeding of healthy stocks.

[7] Ibid., p. 381.

No review of recent work on diphtheria control would be complete without emphasizing the clinical application of laboratory experience of administration of biological products. In treating an acute infection like diphtheria, where time is valuable, the intravenous route has the great advantage that a given dose of serum is made instantly effective, whereas many times this dose injected intramuscularly is followed by a useful blood concentration only after the lapse of some time. Even 48 hours after intramuscular injection the level of demonstrable circulating antitoxin, which is usually the peak level, is only half the concentration attained at the outset by intravenous injection of the same dose. The conclusion of the laboratory worker is that there would be fewer failures in serum therapy if clinicians would decide quickly on the number of units the acute case is likely to require and give as much as possible intravenously. With regard to diphtheria prophylaxis, the first dose should contain a useful amount of antigen; 0.2 c.cm. (10 Lf. units) of the A.P.T. now available in this country would meet this requirement. The second dose may be very small (Glenny[8]) if the first dose has paved the way for a "secondary stimulus response." As only a limited number of persons are sufficiently "primed" by the first dose, it is advisable to give a relatively large second dose—namely, 0.5 c.cm. The interval between doses of A.P.T. should be long, preferably four weeks, a recommendation adopted by the Ministry of Health. A third dose after a long interval, say one year, usually produces an even more rapid and extensive rise in circulating antibody. Indeed, the advantages of periodic restimulation by "re-call" or "boosting" doses should never be overlooked in active immunization, not only against diphtheria but also against other bacterial diseases, such as the enteric fevers and tetanus.

DIETETICS OF PREGNANCY

At a time when millions of the world's adults are concentrating their efforts on killing as many other adults as possible, it is a curious paradox that medical and nutritional attention should be directed more intently than usual to the insistent problem of saving neonatal and infant lives. Yet the comprehensive review by Huggett[9] on the nutrition of the foetus, the subject of "Diet in Pregnancy" chosen by W. C. W. Nixon for the Blair-Bell Memorial Lecture,[10] and recent highly significant "field" experiments all point to an awakened interest in those processes of nutrition that bear on the health of the human organism during the period of six months to twenty months after the act of fertilization. Huggett's survey of the profound and rapid changes that take place during the last three months of gestation makes a sound physiological background for the demand, now almost universally supported, that these months of foetal life should be regarded for rationing purposes as those of an independent organism. The close connexion between diet and the hazards of pregnancy is further emphasized in the recent paper by Nixon, Wright, and Fieller,[11] who find a highly probable correlation between sub-optimal intakes of aneurin and the incidence of oedema and pregnancy toxaemia. A recent study by Williams and Fralin[12] has confirmed for the pregnant women of Philadelphia what Orr, M'Gonigle, and many others have shown for non-pregnant adults in this country and in the U.S.A.—that there is a progressively increasing intake of certain nutrients, specifically those found in the protective foods, as income rises. Their subjects, according to their own statement, failed to demonstrate "any positive relationship between dietary adequacy and the occurrence of certain complications of pregnancy and childbirth"; yet this is not altogether consistent with their observation that "84% of a group who presented a history of nausea and vomiting in early pregnancy had an intake below the pregnancy standard of 600 units of vitamin B_1." It must be noted, moreover, that of their 514 cases only 10 were receiving diets that "could be termed good," so that positive controls were largely lacking in this investigation.

A different and clearer picture is shown by the study made in Toronto by Ebbs, Tisdall, Scott, Moyle, and Bell,[13 14 15] who set out to "determine the effect of poor and good pre-natal diets upon the outcome of pregnancy and condition of infant during the first months of life." The investigation comprised only those patients who had not completed six months of pregnancy, and who agreed to be confined in the Toronto General Hospital They were divided into three groups. 120 women formed the "poor-diet group." The second group was made up of 90 women "who had been on an equally poor diet as the first group until the 4th or 5th month of pregnancy, and whose diet was then specially supplemented," the fund for this being provided by a Toronto business man. The third group, of 170 women, were found to be on "moderately good" diets, and to have enough money to provide a "good diet" if given advice. The Toronto workers aimed at giving daily the following amounts of essential foods: 40 oz. milk, 1 oz. cheese, 1 egg, "an average serving" of butter and meat, two servings of vegetables in addition to potato, 1 orange or half a grapefruit or 5 oz. of tomato juice, one half of the cereals and bread consumed to be in whole-grain form, and 2 teaspoonfuls of cod-liver oil or equivalent in concentrate; liver once a week; salt to be iodized, and medicinal iron to be used if indicated; 2 tablespoonfuls of wheat-germ daily were also advised. "Past history" showed that those patients on a poor diet had a much higher incidence of previous obstetrical complications than those on a good diet. Some of the end-results of the Toronto experiment were as follows: In the poor-diet group there was threatened miscarriage in 8.4%, in 1.1% of the group receiving a supplementary ration, and in 2.4% of the good-diet group; there was actual miscarriage in 6% on a poor diet, none in the group receiving supplementary ration, and 1.2% in those on the good diet. For the three groups in the same order there was premature birth in 8%, 2.2%, and 3%; stillbirth in 3.4%, 0%, and 0.6%; and toxaemia in 7.6%, 3.4%, and 3%. The average haemoglobin values at term were: in the poor-diet group 11.5 g., in the group receiving supplementary ration 12.1 g., and in the good-diet group 11.9 g. The average birth weight of the babies born to mothers of the poor-diet group, the supplementary group, and the good-diet group, respectively, were 7 lb. 10 oz., 7 lb. 7 oz., and 7 lb. 6½ oz. The authors intend to follow the progress of the babies in these three different groups in order to determine whether the pre-natal diet has any effect on their development. They give a brief summary of their observation on the first 250 babies up to the age of 6 months. Breast-feeding whilst in hospital was carried out by 81% in the poor-diet group, 95% in the supplementary diet group, and 88% in the good-diet group; 6 weeks after birth these figures had changed to 59, 86, and 71 respectively. In the first 6 months 3 babies from the poor-diet group had died, and none had died in the other two. In the poor-diet group 21% had frequent colds, the percentage being 4.7 in each of the other two; the corresponding figures for pneumonia were 5.5, 0.5, and 0.9. Rickets was observed in 5.5% of the infants in the poor-diet group, none of the supplementary diet group, and 0.9% of the good-diet group. Anaemia was present in 25% of the poor-diet group, 9.4% of the supplementary diet group, and 17.1% of the good-diet group. The authors' conclusion that mothers on a good or supplemented diet had better health and fewer complications and were better obstetrical risks than those left on the poor pre-natal diets seems to be fully justified, as does their observation that the health of infants was poorer in the poor-diet group. They observe that "in a large proportion one could tell the diet group of the mother by looking at her baby."

The Toronto experiment receives support from the results of an investigation carried out under the auspices of the People's League of Health[16] from March, 1938, to the end of 1939. The matter investigated was the effect on the course of pregnancy and labour and on the newborn child of a vitamin and mineral supplement to the daily diet. Out of 5,022 women, 1,000 gave a record of food normally eaten in one week. From this evidence it appeared that 70% were not taking enough calcium and 98% not enough iron. Vitamin A deficiency was common, and some 50% were not taking enough vitamin C. The women were given supplements of iron, calcium, iodine, manganese, and copper, and of vitamins A, B complex, C, and D. The toxaemia rate among 1,530 primigravidae on the supplemented diet was 27.1%, as against 31.7% among 1,512 primigravidae in a control group. On this basis, and with an average of 600,000 births yearly in England and Wales, the saving of 10,000 cases of toxaemia could be effected yearly by dietetic means alone. It was also found that premature birth was less frequent among primigravidae on the supplemented diet than in the control group.

Many of those who are interested in these problems—and probably some who have taken part in the work outlined above—will doubtless be present at a symposium that bears very closely on the matter and is being arranged by the Nutrition Society on "Diet in Pregnancy" for an early date in the New Year, when we may expect further light to be shed on some of the many still obscure points.

INFLUENZA PREVENTION

If the concerted attack now being made on air as a vehicle of infection succeeds in its aim, perhaps the greatest benefit achieved will be the prevention of acute catarrhal infections of the air passages. Although other air-borne infections may be more serious, none causes more inconvenience and disability, for no other produces illness on such a scale or recurs with such frequency. That some of the methods recently evolved can actually disinfect an atmosphere laden with the virus of influenza and so prevent its spread is proved by the experiments of J. Stokes and W. Henle.[17] These were conducted in an infants' ward divided into sixteen cubicles, where the patients were replaced by mice. Suspensions of highly mouse-virulent influenza A virus were atomized in this room, and in a control experiment every one of 70 mice exposed in different parts of the ward died with influenzal lesions. Atomization of virus was carried out for the same period with ultra-violet light irradiating the whole of the upper air of the ward and directed as a barrier across the entrance to each cubicle: the only mice dying in this experiment were three of those in the cubicle containing the atomizer, some of the mice in adjoining cubicles having non-fatal influenzal lung lesions. In a third experiment propylene glycol was vaporized to give an air concentration of between 1 in 2,000,000 and 1 in 4,000,000: all the mice survived, and only 3 which had been in the same cubicle as the atomizer showed influenzal lesions when killed. Although it is well recognized that ultra-violet light will destroy influenza virus, this is the first evidence, so far as we know, that propylene glycol will do so, and the evidence has been obtained in a highly significant form, under conditions which enable this conclusion to be translated directly into practice. The authors have also been able to test the efficacy of propylene glycol in practice: a concentration of about 1 in 30,000,000 was maintained in the air of a children's ward for seven weeks in mid-winter, and during this time the incidence of respiratory infections fell almost to *nil*. It should be recollected that propylene glycol vapour is imperceptible and presumably quite harmless, since the liquid itself can be swallowed in quantity without ill effects. The very encouraging observations reported by these authors include an experiment in which human volunteers, some of whom had been given influenza virus vaccine, inhaled through aviation oxygen masks an atomized suspension of influenza virus recently isolated from a fatal case. Of the controls 35% and of the vaccinated only 3% developed clinical influenza. The longest interval between vaccination and exposure was only 18 weeks, and this may perhaps explain the efficacy of the protection afforded; the balance of evidence, as we pointed out recently,[18] is unfavourable to this method. Of the three proceedings studied, aerial disinfection by means of propylene glycol appears to be the simplest and perhaps the most successful; unless it should prove to have unexpected drawbacks it should have a wide field of application, particularly in hospitals and possibly elsewhere.

LYMPHOPATHIA VENEREUM

The diagnosis of this disease, often known in this country as lymphogranuloma inguinale (synonyms—climatic bubo, poradenitis, Nicholas-Favre disease), presents considerable difficulties, because the initial lesion is evanescent and, in fact, usually overlooked, while inguinal adenitis may be due to a variety of conditions. There can be little doubt that lymphopathia venereum is far commoner than has been realized, more especially in tropical and sub-tropical countries and in parts of the U.S.A., where it is particularly frequent among negroes. Hitherto most venereologists have relied on the intracutaneous test of Frei[19]: Frei's antigen, made from human bubo pus, has proved highly specific, but the supply, for obvious reasons, is difficult to obtain and maintain. Recently antigens have been made from the brains of infected mice, but these have not proved entirely satisfactory. More recently still it has been found that the virus of lymphopathia venereum can be grown on the chorio-allantoic membrane of the developing chick embryo, and from this source an antigen known as "lygranum" has been obtained which is free from many of the objections raised against the other two.

Lygranum is essentially a saline suspension rich in virus elementary bodies prepared from chick embryos; it is freed from most of the tissue constituents by differential centrifugation and is formalinized to inactivate the virus. It can be used either for the skin test or for serum complement-fixation. For use in both it is standardized by dilution to a strength which is found to give a positive reaction in known cases of lymphopathia venereum and a negative one in normal persons. Control material is prepared from normal chick embryos. The skin test is performed by injecting 0.1 c.cm. of lygranum into the skin. Readings are taken at 48 and 72 hours, and, if necessary, again at the end of a week; a positive result is indicated by a papule not less than 7×7 mm., and a negative by one less than 5×5 mm. A papule intermediate between these two is considered doubtfully positive. Shaffer, Rake, and Grace,[20] and Axelrod[21] found lygranum to be both highly sensitive and specific for skin tests; it was at least equal to human pus antigen and superior to that prepared from infected mouse-brain.

Results with the three forms of antigen were as follows: In 106 persons diagnosed as having lymphopathia venereum lygranum gave 96 positive, 3 doubtful, and 7 negative results; with mouse-brain antigen there were 78 positive, 9 doubtful, and 19 negative reactions. In 42 of the above cases human pus antigen gave 38 positive, 1 doubtful, and 3 negative reactions. Shaffer and his colleagues also found lygranum to be most satisfactory in the complement-fixation test; in 115 persons diagnosed as having lymphopathia venereum the sera of 113 gave definite positive reactions; the two failures occurred in cases of rectal stricture which were also Frei-negative. The interesting observation is made that skin sensitivity often disappears after sulphanilamide therapy and that apparently the disease is not passed from mother to child *in utero*. Another interesting observation is that in 70 persons, either normal or suffering from diseases other than venereal, positive results were obtained by complement-fixation tests in 6 and negative ones in 64, while of 60 persons suffering from venereal disease 31 gave positive and 29 negative results. From this it is concluded that infection with the virus of lymphopathia venereum is often acquired at the same time as other forms of venereal disease.

There can be little doubt that lygranum possesses many advantages over other forms of antigen for skin tests. It is both highly sensitive and specific; it is obtainable in bulk and is not dependent on supplies of human pus; moreover, it constitutes an antigen for use in skin and complement-fixation tests more efficient than any hitherto produced. The intravenous use of chick-embryo antigen is said to give unsatisfactory results as compared with mouse-brain antigen,[22] but few venereologists employ this route.

SUPPLIES FOR PATHOLOGICAL LABORATORIES

One of the many ways in which the health services of the London County Council are assisting the war effort is the subject of a recent report. The comprehensive pathological service provided by the L.C.C. for several years past has greatly extended since the war began and has become the basis of a national system for the supply of material essential to the maintenance of the laboratories of the Ministry of Health and of the Army. The Council quite early adopted a centralized system for the purchase of laboratory requisites and the manufacture of culture media, vaccines, stains, and so on. The laboratory materials are prepared at a "media establishment" attached to one of the group laboratories, with branch accommodation at a mental hospital. In the early part of the war, when the Ministry of Health found it difficult, if not impossible, to meet the needs of the new laboratories in connexion with the Emergency Hospital Service and general public health investigations, the L.C.C. agreed to supply all the emergency laboratories in the London region with culture media and other materials. Recently the Ministry asked the Council to extend the provision to the whole of the Ministry's laboratories which have been set up in the Provinces, and this has been done. Some years ago the Army authorities adopted the L.C.C.'s system of supplying media in screw-capped bottles for use in the event of hostilities, and on the outbreak of war it seemed to all concerned that the simplest and most economical method of obtaining Army culture media would be to use the resources of the L.C.C., which had the plant, the trained personnel, and stocks of material available. The request of the War Office was acceded to, and Dr. J. E. McCartney, director of the Council's group laboratory, who had been mobilized in the Territorial Army with the rank of major, R.A.M.C., and appointed officer commanding media manufacturing centre for the British Army, was allowed to remain attached to the group laboratory, undertaking not only his peacetime work but the large extensions which have since occurred. It is estimated that the additional requirements (which include the supply of culture media from the Council's resources to allied nations) will be equal to 75% of the total quantity produced. All this is in addition to other special work of national importance undertaken at the group laboratory and the antitoxin establishment, such as the supply of certain antitoxins and measles serum to local authorities in some reception areas. diphtheria prophylactics to metropolitan borough councils. and a large quantity of tetanus antitoxin to the Medical Research Council for a national pool. Gas-gangrene antitoxin has also been prepared in case of need.

LUNG-DUSTING EXPERIMENTS

Barclay, Franklin, and Macbeth have already reported[1] [2] on x-ray studies of excretion of dusts from the lungs. In a more recent paper[3] Barclay, Franklin, and Prichard describe further experiments which correct an erroneous conclusion previously formed, and increase our knowledge of dust inhalation and excretion, phenomena of importance to both clinician and industrial hygienist. Cats were used, and both insufflation and inhalation methods were carried out. Various dusts opaque to x rays were employed, from finely powdered lead glass with particles up to 45 μ in size to uncompressed gas-flame carbon with particles about 0.5 μ in size. Control radiographs were taken before and immediately after the dustings. The lungs and trachea were immediately excised and x-rayed, and additional radiographs were taken after fixation of the lungs and the removal of portions for histological examination. In discussing their results the authors consider certain points established beyond dispute. In all the subjects there was some introduced dust in the alveoli; this corrects an earlier conclusion when delayed histological examinations gave negative results. Although the amount of alveolar dusting varied greatly from subject to subject, it was never so great as to be detectable with certainty in the radiographs, even of excised lungs. This was in strong contrast to the obvious bronchiolar dusting. Finally, the amount of alveolar dusting did not run parallel with the amount of bronchiolar dusting as seen on histological examination. Almost identical quantities of a particular dust could be present in the alveoli of two subjects, while the bronchioles and bronchi of one were loaded and of the other practically clear. Therefore the condition of the tubular system, readily assessed when radio-opaque dusts are used, is no guide to the alveolar condition in any particular case. These observations indicate the apparent existence of a defence mechanism preventing the entry of large quantities of dust into the alveoli. The experiments suggested, but did not prove, that the average amount of dust entering the alveoli is the same in insufflation and in quiet and gasping respiration. Apparently, also, introduced dusts collected in relatively greater amount in inflamed areas of the lung. This has a highly important bearing on problems of industrial pulmonary disease.

[3] *Amer. J. Roentgen.*, 1942, 47, 362.

In healthy subjects the total elimination of small amounts of dust from the alveoli can be a rapid process (Seemann,[4] Carleton[5]). Barclay, Franklin, and Prichard found that in some cases the alveolar dust-cells were found to have ingested dust particles within a few minutes of their penetration into the alveoli. They found no evidence of dust deposition in the bronchial lymph glands. It appeared that normally the loaded alveolar cells moved towards the ciliated epithelium of the bronchioles, were caught up on the layer of viscid mucus, and carried up with it by the action of the cilia. The dust is thus brought back to the pharynx. When the insufflated dusts were washed down into the alveoli by subsequent intratracheal injections of a few c.cm. of fluid the excretion of dusts from them was very much delayed. In this case the delay was presumably due to overwhelming of the protective mechanism by the actual quantity of dust carried down by fluid. In man, chronic irritation of the air passages leads to replacement of the ciliated epithelium by cells of the goblet type, and in addition there is a greatly increased production of mucus by the buried glands. Thus the above excretory mechanism would be interfered with in two ways, and coughing becomes necessary to clear the bronchial tree. This explanation throws much light on the effects of upper respiratory infection on the lungs—effects commonly observed by the clinician. Finally, it will not be without interest to refer here to some recent experiments of Campbell.[6] He showed that in mice the inhalation of a precipitated silica produced nodules in the tracheo-bronchial glands in 50% of the animals. These nodules resembled the classical fibrotic silica nodule in man. The nodules were, however, not produced in the lungs of the mice, and this was considered to be due to the fact that most of the dust had been removed to the lymph glands and the degree of dusting was not enough to affect the lungs also. These results gave support to the specificity theory for silicosis.

THE CAUSES OF INFANTILE MORTALITY

As C. McNeil pointed out recently in these columns[7] the infantile death rate in Great Britain is still nearly twice as high as in certain other countries—notably Holland and New Zealand. The first step towards a reduction is a clear understanding of the cause, and paediatricians have long been dissatisfied with statistics based upon death certification. In 1939 a study was undertaken in Newcastle-upon-Tyne, and an investigator[8] with modern clinical experience of disease in infancy made a personal and detailed inquiry into the circumstances of the death of every child below the age of 1 year. In this investigation J. C. Spence and F. J. W. Miller secured the co-operation of practitioners who were ready and anxious to impart full information—information which showed that in one-third of the cases the recorded cause of death gave an inaccurate or inadequate description of the actual cause. An arrangement was made whereby the name and address of each child dying in the first year of life and the name of the doctor signing the certificate were sent to the investigators within twenty-four hours of the registration of the death. Contact was made at once with the doctor, the object of the investigation explained, and a personal interview arranged at which the history of the final illness and the events leading up to it were discussed and recorded on a special form. Wherever possible, additional information was obtained from antenatal records, infant welfare charts, hospital notes, and, in about 20% of cases, by the result of a post-mortem examination. Altogether 272 deaths were investigated, and in 231 it was possible to express an opinion upon the cause of death. In the neonatal period the most important causes were prematurity (47 cases), birth-death (infants so subjected to adverse conditions during birth that they failed to survive—38 cases), and neonatal infection (15 cases), though it is thought that the actual incidence of neonatal infection was greater than the apparent. Actually, if the accepted standard of 5½ lb. or less birth weight for prematurity is taken, there were 78 deaths, or more than a quarter of all the infant deaths. In the period after the first month the chief causes of death were infective conditions, which caused death in 90 out of 112 cases in which an opinion could be given. It was not possible to assess with accuracy the exact type of infection responsible for death in every case, and there is clearly great scope here for future and valuable research. Roughly, three groups were recognized: illnesses with respiratory symptoms 33 cases, with alimentary symptoms 12 cases, and infections of unknown origin 32 cases. The relatively small number of infant deaths directly attributable to gastro-enteritis may be surprising to those accustomed to assume that diarrhoea and vomiting mean primary infection of the alimentary tract. That infection of the respiratory tract is nowadays—i.e., with the disappearance of "summer diarrhoea"—the more serious problem needs repeated emphasis, but this must not detract from the fact that, in the opinion of the Newcastle investigators, an increased incidence of breast-feeding would assist materially in a reduction in the number of infant deaths. Only 17 out of 98 infants dying from infections of various types had been breast-fed until 6 months of age or to the time of death.

Although Spence and Miller apologize in their conclusion for failing to find the predisposing and immediate cause of death in a large group of their cases, they have performed a most valuable task in providing exact knowledge upon which to base future work. It is clear that the problem of deaths in the first month of life is quite different from that after the first month, but at both periods it is essential to get rid of what they term "a spirit of resignation" towards the whole problem of infantile mortality. A conscious and united effort on the part of medical practitioners, medical officers of health, and hospitals working in conjunction with trained paediatricians would go far to achieve those lower rates in other countries which C. McNeil has pictured as a goal for preventive paediatrics in its future development.

Nova et Vetera

NICHOLAS ALCOCKE, SURGEON TO HENRY VIII AND EDWARD VI

I should assume that Nicholas Alcocke was born about the year 1500. The first notice that we have of him at Barbers' Hall is his admission to the Freedom of the Company in 1523. The usual period of apprenticeship was seven years, and the apprentice was generally between 14 and 16 years of age at the date of the signing of his indentures. It is rather an odd thing that Alcocke seems to have taken no further interest in the company after his admission to the freedom. He never served the office of Warden. He appears in the Holbein picture and is one of the kneeling figures, being placed immediately behind Pen and in front of Ferris. As he was not holding office in the company at that time I assume that he owed his inclusion to the fact that he was one of Henry the Eighth's surgeons. This indicates that the picture was painted after the year 1539, for his warrant of payment as King's surgeon is dated in that year, as I shall presently show.

Sir D'Arcy Power, in *The Craft of Surgery*, says that the picture was probably painted in 1542. Vicary, who is receiving the deed, was Master in that year, and the fact is noted that Holbein died of the plague in 1543. Only two of the figures standing to the left of the King can be identified. They are William Tilley, who was Middle Warden in 1540, and Christopher Salmon, who was Junior Warden in 1543. It should be remembered that the elections to office at the Hall were made in the late summer of each year.

To return to Alcocke's warrant. This ran: "Nicholas Alcoke, Surgeon, by the Kingis warraunt dated XX day of November anno XXXJ (1539) for the yerely payment to him of X li. by yere, quarterly by even porcions from Mychaelmas dicto anno XXXJ during his lyf; the somm of L s. for one quarter fully ronne ultimo Decembris dicto anno XXXJ." Payments of fifty shillings a quarter are recorded in the public records during the years 1540, 1541, 1543, 1544, and 1547.

In 1542 Alcocke had a grant in fee, as one of the King's surgeons, for £173 5s. of the Rectory of Kirby, Lincs (late Elsham priory), with tithe-barn and stable, in the tenure of William Turwytt; also the advowson of Kirby. This grant is dated 5 May 34, Henry VIII. In 1544, in a list of retinues for France, Alcocke is allowed one billman; and in the same year is an order to pay Nicholas Alcocke 2s. a day from July 1 and sixpence for two servants, for the war. In 1545 he was granted the lease of a tenement at Freshe Wharffe, in St. Botolph, Billingsgate (late St. Mary Graces). This is dated May 25. In the same year he had a licence to export 300 cloths, "unbartred, unwrought and unshorn," dated October 18; and on February 20, 1545/46, he was appointed Bailiff and collector of rents of Merevale, Mon. He also asks for leave for Arnolde Kyrkman of Cologne to bring into England an English version of *Magnus Herbarius*. Between 1547 and 1551, in *Early Chancery Proceedings* is the record of "the case of Nicholas Alcocke *versus* Thomas Pyke, of London, Skinner, *re* a messuage in Freshe Wharfe, late of St. Mary Graces." As Alcocke dealt with this property in his will I suppose that he proved his title.

According to Young, in the *Annals of the Barber-Surgeons' Company*, Alcocke died in 1550. Young gives a very good abstract of his will, which was dated 15 Feb., 1549/50, and proved 6 May, 1550. Alcocke desired to be buried in St. Stephen, Coleman Street, near the graves of his children. He bequeathed his goods in three parts: one part for the purposes of his will; one part for his wife, Margaret; and one part for his daughter, Elizabeth, when she should reach the age of 21 or be married. This custom of tripartite division into wife's part, bairns' part, and the dead's part is a very ancient one. A celebrated example can be found in the works of the Venerable Bede.

Alcocke ordered six sermons to be preached at St. Stephen, Coleman Street, and left to the poor of Swyneshed, Lincs, £5; for poor maids' marriages, £4; to St. Bartholomew's Hospital, £2; to George Brykesworth, of Glastonbury, Surgeon, his best lute; and to his daughter, Elizabeth, his virginalls. He left clothes, boots, and "a paire of spurres" to his servant, Richard Sygans, and a bedstead, mattress, and coverlet to his maidservant, Ann. To Robert Balthrope,* "late my apprentice, my booke *Guido*, in Englysshe." There are bequests of pewter dishes and saucers to his godchildren, the daughters of Robert Wilson and John Stocks; "to John Mason, late my apprentice, Lanfrank, John Arden, an other olde booke with a bare woodden cover in Englysshe and the practice of Ypocrates." To his wife's father, Thomas Turnor, various clothes, and a similar bequest to the eldest son, his brother-in-law. To Robert Balthrope my "Russett woorsted gowne faced with calaber and garded with velvett." The great house called "ffreshe Wharff," of annual value £24, to his daughter. If she died before coming of age this wharf to be sold and divided in certain proportions between St. Bartholomew's Hospital, his father-in-law, Thomas Turnor, and Richard his son, the poor of Coleman Street, poor maids' marriages, and the mending of highways. He left certain pastures and meadows at Enfield to his wife; Kirby parsonage with tithes and profits to be sold and 100 marks given to Roger Alcocke, his brother's son; 20 marks to godson Nicholas Spencer, and the residue in works of charity at the discretion of his executors, Thomas Archer, gentleman, and Randolph Atkinson, Merchant-Taylor. He made John Wysdome, Painter-Staynor, and John Shireff, Barber-Surgeon, overseers of his will. On consulting the will of Robert Balthrop, which is also given in Young's *Annals*, I find that "*Guido* in Englysshe" was left to his former servant (i.e., apprentice) John Edwards, but I cannot trace the "Russett gowne"; perhaps it was worn out. The calaber with which it was faced was probably squirrel's fur. Bequests of wearing apparel of this sort are very common in mediaeval wills. It must be remembered that the clothing of the upper classes at this date was costly. The gown of a gentleman was a voluminous affair, and would take several yards of cloth in the making, not to mention the fur.

R. R. J

CURIOSITIES OF CAESAREAN SECTION

I have come across an account of a remarkable case of Caesarean section performed some 150 years ago, which I think will be of interest to your readers.

It is related by Mr. Duncan Stewart, surgeon, in Dungannon, who saw the patient some days after the operation; and the account is confirmed by Dr. Gabriel King of Armagh, who says that he drew out the needles which the midwife had left to keep the lips of the wound together. The patient's name was Alice O'Neil, and the operator was an illiterate midwife, one Mary Dunally; the instrument used was a razor, with which she first cut through the containing parts of the abdomen, and then the uterus. "She held the lips of the wound together with her hand, till someone went a mile and returned with silk and the common needles which tailors use; with these she joined the lips in the manner of the stitch employed ordinarily for the hare-lip, and dressed the wound with whites of eggs." The woman recovered in twenty-seven days.

It is also of interest to note that at this time foreign jurists doubted whether a child extricated by the Caesarean operation was properly born or capable of succession. "Illud autem valde controversum est inter jurisconsultos, an is qui editus est execto matris ventre reputetur partus naturalis et legitimus et successionis capex" (*Caranza de partu naturli et legitimo* p. 427).

Shakespeare, in *Macbeth* (Act IV, Scene 1), utilizes this quibble in an ingenious form:

> *Second App*: Macbeth! Macbeth! Macbeth!
> Be bloody, bold, and resolute; laugh to scorn
> The power of man, for none of woman born
> Shall harm Macbeth.

And again, in Act V, Scene 8:

> *Macduff*: And let the angel whom thou still hast serv'd
> Tell thee, Macduff was from his mother's womb
> Untimely ripp'd.

The child born by the Caesarean operation, I need hardly say, does not suffer any legal disabilities.

*Later Serjeant-Surgeon.

Correspondence

Notification of Venereal Disease

SIR,—I agree with Dr. Edith Summerskill that Defence Regulation 33B is a great disappointment. Frankly, it appears to me that the Ministry of Health has "missed the bus." Here was an opportunity to deal with the problem of venereal diseases in a comprehensive way, and instead we get a miserable regulation that will result in the rounding up of a prostitute here and there. Perhaps now and again a couple of soldiers may be found who are willing to testify to infection from the same source—a man loses his individuality in the Army—but it is most exceptional to find two civilians who are able or willing to do so. As regards civil life, therefore, in my experience the regulation will remain a dead letter.

I am not, however, prepared to go the whole way with Dr. Summerskill in advocating compulsory notification of all venereal disease. The risk that it would result in concealment is too great. In my humble opinion what is needed is a limited form of notification. Congenital syphilis should be notifiable, just as ophthalmia neonatorum is, and the parents as well as the child should be compelled to have treatment. It is a duty we owe to the children and to the nation. Ophthalmia neonatorum is already notifiable, but the parents are not compelled to have treatment. The public would be horrified if it knew how many syphilitic children are born every year, and what a large proportion of these receive no treatment until various disabilities, many of them developing at school age, affect them. But prevention is better than cure, and I am heartily in agreement with Dr. Summerskill when she advocates a compulsory blood test for all pregnant women. For years now I have advocated that this should be carried out in the maternity and welfare clinics of our local authority. I have no hesitation in saying that congenital syphilis can be reduced to negligible proportions if a blood test, followed by treatment in positive cases, is carried out. "If preventable, why not prevented?" At my ante-natal session blood is taken as a matter of course, and no questions asked.

To come back to notification, a doctor who undertakes the treatment of venereal diseases in an official capacity should have the power to report the case to the medical officer of health only if the patient refuses to continue treatment while still infectious. Simply to render it an offence not to obtain treatment, as suggested by one speaker in the House of Commons, would not meet the case. Nowadays people, even prostitutes, come up for treatment and are extremely anxious to receive it. The trouble is that, having obtained a certain measure of relief, a large proportion default while still infectious, and no almoners, no personal appeals, and no reminders by post have any effect whatever. It is these callous and selfish people who go around spreading infection that we want to get at.—I am, etc.,

Sunderland

NOEL F. ROWSTRON

Paying for V.D. Treatment in Mental Hospital

SIR,—A patient of mine with central nervous system symptoms and a positive Wassermann reaction was referred by me for treatment to a clinic for venereal diseases under the local authority. While undergoing treatment there he was, by arrangement with the M.O. in charge and on his advice, referred to a mental hospital for malarial therapy. In this area—and probably in others—assessments for mental hospital treatment are made by the public assistance committee and not by the health committee of the local authority. In due course this patient received an account for his stay in the mental hospital. He has drawn my attention to the well-known proviso that treatment for venereal diseases is widely advertised as free and confidential. The resulting dilemma would appear to be in such cases that if a patient resists the demand for payment by claiming that his treatment should be "free," then *ipso facto* he has to divulge to a lay assessment committee the nature of his complaint. If, on the other hand, he "pays up" to avoid disclosure and trouble, then the provisions of the free treatment promised are not fulfilled.

The dilemma is not quite as simple of solution as might be imagined. It is obvious that many of the patients of public mental institutions are there because of tertiary syphilis, and local authorities may be reluctant to forgo the right they claim to make assessments in cases like that outlined above because of the far-reaching implications, especially as regards expense. In short, I ask those more in a position to know, What is the general policy pursued by local authorities about the treatment in mental institutions of tertiary syphilis as regards its "free and confidential" aspects?—I am, etc.,

GEOFFREY H. BARENDT

Myasthenia Gravis

SIR,—The article on drugs for myasthenia gravis (Dec. 19, p. 730) prompts me to record the following case. In June, 1935, I was asked to see a dental surgeon, male, aged 50 years, who complained that recently he had experienced increasing difficulty in masticating and swallowing solid food. Examination elicited the fact that there had been during previous months some loss of muscular power generally, ptosis, weakness of the orbicularis and soft palate, with tendency to nasal regurgitation of food. Exercise resulted in undue fatigue. He was, in fact, a typical case of early myasthenia gravis.

He was at once put on to injections of prostigmin commencing with ♏ 5 t.d.s. together with ephedrine by the mouth. This treatment was continued for some months, but in spite of increased doses of prostigmin up to ♏ 20 t.d.s. the patient's condition rapidly deteriorated. Muscle weakness increased until he was unable to stand for any length of time. He was unable to hold his head up, and the typical attitude adopted was to sit, resting his elbows on a table and supporting his chin in his cupped hands. Ptosis became very pronounced and no solid food could be taken. Everything had to be fluid or semi-solid or minced. Throughout the whole time there was no muscle wasting. He had become dull and apathetic, taking little interest in things generally. By this time he had been obliged to give up practice completely. The prostigmin and ephedrine had no effect whatever on the progress of the disease. The only advantage had been that, if administered about half an hour before meals, there was a temporary muscle stimulation or recovery sufficient to enable him to deal with his food rather more satisfactorily than otherwise. Urine examination showed the creatinine output to be very low, approximately 0.15 g. per diem.

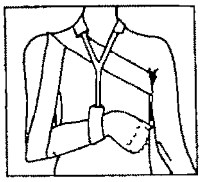
Some three months after the above treatment was started the possibility of glycine (amino-acetic acid) being of benefit was considered. Treatment with ℥ss doses t.d.s. was begun with startling and spectacular results. There was an almost immediate improvement. Within a very few weeks my patient was able to masticate his food much more easily. The ptosis improved, as also did the neck muscles; in fact there was a steady improvement in every direction. He began to take more interest in life, urine examinations at intervals revealed a steady increase in the creatinine output until the normal of about 1.2 g. daily was reached. The dosage mentioned above was maintained for about 1½ years, by which time he had made such considerable improvement that he was able to take a substantial share in the conduct of his practice. The dose of glycine was then gradually reduced, a careful watch on the creatinine output being kept to ensure that it did not fall below normal. At the slightest sign of such a fall the dose was increased accordingly. All went well until, early in 1938, the patient began to show symptoms of bladder disease—i.e., frequency, haematuria, etc. An investigation showed the presence of a papillomatosis of the bladder, from which he died a few months later.

Myasthenia gravis is generally regarded as a disease of the central nervous system, although no definite recognizable lesions have been noted in the brain or spinal cord. My observations from this case suggest that the disease is rather a condition brought about by some alteration in the body metabolic process, which results either in the storing up of creatinine, possibly in the muscle tissues, where it acts as a muscle poison, or in a decreased creatinine (or creatine) metabolism resulting in the muscles being deprived of the element required to stimulate contraction. My grateful thanks are due to the British Drug Houses Ltd., who generously provided the glycine required throughout the whole period of treatment.—I am, etc.,

London, N 22 S. CHAPLIN.

Treatment of Dislocated Acromio-clavicular Joint

SIR,—Necessity is often the mother of innovation as well as invention, and especially is this so in the realms of medicine and surgery when a new use is found for an old appliance. The treatment of the dislocated acromio-clavicular joint with its associated tearing of ligaments is notoriously difficult, and one occasionally sees considerable disability due to an old injury of this type. These injuries, if recent, are now being treated by a new method in the orthopaedic department of this hospital.



It was decided that any form of treatment which did not obtain and maintain constant full reduction should be discarded. The following lines of treatment, though standard, were weighed in the balance and found wanting: (1) Adhesive strapping of various types, including "elastoplast" extension strapping applied as recommended by Watson-Jones, in conjunction with a sling. Even if several layers thick, this works loose and needs renewing—i.e., reduction is not constant. (2) Tight flannel bandages extending under the elbow, over the shoulder, and round the opposite axilla. (3) Tight "cellona" bandages applied in the place of the flannel.

Constant full reduction *can* be obtained and maintained for a considerable period of time without readjusting by using an Esmarck tourniquet as a bandage, in conjunction with a sling. This method gives and maintains full reduction and a perfect functional result, and would justify more widespread use.—I am, etc.,

V. F. MASTERS,
Berkhamsted. Orthopaedic Registrar, Ashridge Hospital

Fulminating Purpura and Adrenal Haemorrhage

SIR,—The following history of a case of fulminating purpura and adrenal haemorrhage, occurring in a remote settlement in North-Western Canada, may be of interest.

The child, a healthy half-breed Indian boy of 23 months, was well until the day of death, Jan. 20, 1933. He suddenly became pale, and his mother noticed a rash developing on his face and arms. Shortly afterwards he went into convulsions, and was dead before a dog team could be harnessed to come to get me. The time from the onset of symptoms till death was less than three hours.

I obtained permission to do a necropsy but not to open the skull. The body was well developed and weighed 27 lb. There were scattered purpuric spots all over the skin, particularly marked on the head and arms. There was no excess of fluid in pleurae, pericardium, or peritoneum. The heart appeared normal. There was slight bronchitis, but no consolidation in the lungs. The stomach and intestines were empty, and there was no evidence of inflammation. The liver and spleen appeared normal. The thymus was not abnormally large, and there was no excess of lymphoid tissue. The kidneys were pale. The suprarenal glands were both deep red and necrotic.

This would appear to have been a case of Waterhouse-Friderichsen syndrome. My reason for reporting it after this lapse of time is that Dr. I. S. Fox in your issue of Aug. 22, 1942, and also Dr. James Hughes in the *Journal* of Sept. 14, 1940, state that this syndrome is usually associated with infection by the meningococcus. It seems extremely unlikely that the meningococcus could have been concerned in this case, for the following reasons.

In a remote and sparsely settled district such as this, it is possible to know with certainty who has been in contact with a patient. The case described occurred in one of four houses separated by 25 miles of forest from the small settlement at Keg River, and by 200 miles from the nearest railroad or large village. I made careful inquiries at the time into possible sources of infection, as I thought I might be dealing with a fulminating case of haemorrhagic measles, scarlet fever, or small-pox. There was no other illness whatever in the same household, none in either of the three houses near by. The only infection prevalent at Keg River was a mild type of influenza, and there had been no recent contact between these cases and the household concerned. It is impossible for a stranger to pass through unnoticed, or unremembered, in a place like this. Air-borne or insect-borne infection can also be safely ruled out where the distance is so great and the temperature 40° below zero.

I can offer no suggestion as to any possible source of infection. It is difficult to imagine that an organism of sufficient virulence to cause a fulminating bacteriaemia could have shown so little sign of its presence in any other member of this tiny community.—I am, etc.,

MARY PERCY JACKSON,
Keg River, Alberta. M.B., Ch.B., M.R.C.S., L.R.C.P.

Haemorrhagic Measles

SIR,—Dr. J. J. Linehan's interesting account of a case of haemorrhagic measles (Dec. 19, p. 725) prompts me to report a somewhat similar case.

A healthy girl of 6 years developed coryzal symptoms on March 21 and a morbilliform rash on March 23. On March 29, after the rash had faded and the symptoms had abated, the temperature rose suddenly and a purpuric eruption appeared on the face. Next day she was admitted to Kendray Isolation Hospital, Barnsley, with large haemorrhagic areas covering most of the face and patches of ecchymoses on the left arm and left thigh. The mucous membranes were not affected: the spleen was not enlarged; there were no joint pains; the temperature was 102° F., with pulse and respiration proportionately increased; scanty albumin was the only abnormal constituent of the urine; blood examination revealed a leucocytosis of 27,300 per c.mm. (polymorphs 80%) but no abnormality of platelets, red cells, or haemoglobin.

For some 48 hours after admission to hospital fresh haemorrhages appeared under the skin of the face and limbs, and haemostatic serum, calcium gluconate, vitamin C, and intramuscular injection of parental blood did not seem to benefit the condition. From April 1, however, no new haemorrhages developed, and the child improved steadily until April 6, when she developed a meningo-encephalitis. By the time she had recovered from this severe complication of measles, all that remained of the ecchymoses was two ulcers on the face and one superficial ulcer on each arm. By June 28, when the girl was discharged from hospital, the ulcers had healed, leaving scars on the cheeks that may later require treatment by plastic surgery.—I am, etc.,

Barnsley I. A. G. MACQUEEN.

Pasteurization of Milk

SIR,—The publicity accorded to the views of Dr. A. H Macdonald, late chief medical officer of Dr. Barnardo's Homes, in your leading article (Dec. 19, p. 727) makes it incumbent upon me to point out that the council of Dr. Barnardo's Homes did not share these views. At their meeting on Dec. 21, 1938, while Dr. Macdonald was still chief medical officer, the council ordered the general use of pasteurized milk throughout the Homes; any departure from this practice would be viewed with grave disquiet.—I am, etc.,

H. CARSON GILMORE,
Dr Barnardo's Homes, London, E 1. Chief Medical Officer

Haemorrhagic Suprarenal Infarction

SIR,—I wonder if this syndrome ever results from disease of the suprarenal arteries? I have in mind the possibility of periarteritis nodosa presenting itself as an acute abdominal emergency demanding surgical measures. Under such conditions, if the vascular changes are not generalized and are obscured by a destructive haemorrhage, the true nature of the condition might conceivably escape recognition. But while the presence of an eosinophilia in any such case would be suggestive, only the verdict of histological examination could be accepted as final. It is nevertheless tempting to question whether the pulmonary, pancreatic, and renal symptoms which sometimes seem to occur in cases of suprarenal infarction may not ever be due to arterial disease of this kind.

I raise this possibility because I have knowledge of one case of periarteritis nodosa presenting itself in the guise of a mesenteric thrombosis (the presence of an eosinophilia in all such cases is therefore worth ascertaining). If, then, periarteritis nodosa can give rise to a mesenteric infarction, may it not also occasionally result in a suprarenal infarction and so produce the syndrome to which Major K. D. Keele has drawn attention in the *Journal* of Dec. 12 (p. 687).—I am, etc.,

Birmingham. GILBERT S. HALL.

X-ray Department at Health Centre

SIR,—I am grateful to Dr. J. F. Brailsford for his letter (Nov. 28, p. 647) amplifying the limitations of the small-powered *x*-ray unit, but I would consider that the 30 mA unit, efficient though it may be for certain types of routine examination in the average size of patient, is less likely to permit accurate interpretation in patients of heavier build in certain types of examination which cannot be considered as other than routine. Furthermore, one must appreciate that the health centre may be the first contact between the patient and his doctor, and that the radiographic findings may have a far-reaching effect on the patient's subsequent treatment; also it is in the centre that one will hope to achieve that earlier diagnosis which may be of such importance.

While agreeing that the expert can decide whether the examination has been adequate, the fact that the patient would be referred to another centre for a routine examination would not instil an air of confidence in the patient or his doctor. The doctor who prefers to have his patient radiographed locally would want to know why his area had not been equipped with an apparatus of adequate power.

With regard to the apparent inconsistency of advocating miniature mass radiography, this method has now passed beyond the experimental stage and beyond the critical scrutiny of committees, and there is little doubt that it would have been adopted at an earlier date had it not been for the fact that suitable apparatus and organization could not be provided without impeding the war effort.

Many favourable comparisons have already been made between miniature and large films, and in a short time I shall hope to be studying a comparison of selected inconspicuous lesions found in the large film and recorded by the miniature method.

The care with which the suspect cases were clinically assessed formed a striking feature of the report recently made by Surg. Captain Brooks on the abnormalities found by the miniature method in 240,000 sailors, and if a similar method is adopted for the examination of the civilian population the success of miniature radiography will be assured.—I am, etc.,

London, S.W.3 J. V. SPARKS.

Rationed Distribution of Doctors?

SIR,—I have read with interest the letter from Dr. Duncan Leys (Dec. 12, p. 708) under the heading of "Rationed Distribution of Doctors?" There is so much controversial matter in this letter that it is perhaps permissible to refer to only a part of its contents. Rationalization is a difficult term to define, whether applied to industry or to medicine, but it should certainly include a due regard for the human element. No evidence that can be accepted has been advanced by Dr. Leys that the plan he proposes would effect a significant economy of medical personnel, and the regimentation of doctors and of the people, with the consequent denial of the freedom of choice which is implicit in the plan, would almost certainly arouse deep resentment. In short, with this plan we should embark on a social experiment of a very doubtful nature at a time when we can ill afford to do so.

Dr. Leys cites his own immediate area and gives, as an example of the effect of putting his plan into operation, an estimate, based on a population of 30,000, of the number of doctors who could be released for service with the Forces. This estimate will not do. The medical specialists centred in Inverness, or most of them, are concerned with a population, which varies with individual specialists, of from 90,000 to 200,000, and there are in some instances additional factors that further invalidate Dr. Leys's estimate. Of the doctors in general practice in this immediate area the majority (perhaps all) are, as part of a very useful form of rationalization, serving the State in different ways as well as attending to their own practices, and two of them are part-time anaesthetists.

There is, of course, a considerable amount of rationalization of the medical services to-day. We see it in the utilization by the State of the services of medical practitioners on recruitment boards, in the War Emergency Hospitals, and in the War Emergency Laboratory Organization. It seems to me that an extension of this rationalization is possible, which would result in closer co-ordination on a regional basis of existing medical facilities with the requirements of the Services, and by increasing the mobility of their medical personnel would go some way towards meeting the growing needs of the Forces.—I am, etc.,

Inverness. H. J. KIRKPATRICK.

Reporting of Deaths to Coroner

SIR,—I have read with interest Dr. W. B. Purchase's letter (Dec. 5, p. 677). It appears to me very retrogressive for any coroner to take steps for private reports to be made to him. Usually the coroner is a legal man (or the perhaps unfortunate combination of legal man with a long ante-dated medical qualification, out of touch with modern medicine and surgery) and in no manner capable of forming an opinion whether inquiry as to death is necessary like an actively practising doctor is (whether private or hospital). Judges frequently refer to communications sent to them or to information already known to a jury, and advise a jury to forget such, and I suggest this is a proper course for any coroner. Dependence on such overtly communicated information must undoubtedly induce a bias in favour of "official" reports, and hence the frequent clash between hospital and private practitioner evidence, which is well shown by Dr. Purchase's own statement: "It may well be that a patient should be sent in much earlier, or that the prior treatment has been inadequate." In a case reported some time ago the evidence of a doctor was rejected in favour of that of a "popular" medico-legal expert, and events showed the doctor to be correct. Equally one often sees protests of general practitioners that their evidence is ignored in favour of hospital evidence, given often by a newly qualified inexperienced doctor.

Particularly in accident deaths a coroner's verdict may deprive dependent relatives of any hope of proper compensation. If certain sections of the medical community are to be influenced to make secret reports, then I see no reason why medical men, employed by insurance companies responsible for compensation, should not be invited to make similar prior reports, a course to which no one would readily agree.—I am etc.,

London, E 7 BERNARD LEGGETT.

Medical Records in Wartime

SIR,—In your annotation (Dec. 12, p. 702) on "Faked Fits and Absent Records" you stress the importance of records from the patient's, and the doctor's point of view. With this most practitioners would agree, but your further statement, "the excuses of a large and busy practice are of no avail," suggests that you are perhaps out of touch with the conditions of wartime general practice. The increase of work resulting from the obligation to attend absent practitioners' patients, the multiplication of certificates demanded, and the inadequate, and in my case non-existent, domestic staff make work on a pre-war standard quite impossible. The essential point is that patients should be thoroughly examined though possibly under-visited and unrecorded.—I am, etc.,

Cheadle Hulme, Cheshire. NICHOLAS CRAIG, M.D.

Electric Convulsion Therapy and Brain Damage

SIR,—In reply to Dr. Horace Hill (Dec. 5, p. 679), I suggest that the point at issue is whether the detrimental effects so far observed outweigh the proved beneficial results, for there is no doubt at all that convulsion therapy will considerably shorten the duration of a manic-depressive psychosis.

No clinical evidence of a permanent defect of brain function has been brought forward although hundreds of cases have been treated during the past two years. Some patients, however, show memory defects of a temporary nature. Prejudiced opinion emphasizes that the treatment is dangerous and empirical, that we are giving the patient epilepsy. It should be realized, however, that, whereas the spontaneous fit is a symptom of disease, in the electrically induced convulsion we are dealing with what Penfield and Erickson (*Epilepsy and Cerebral Localization*, 1941) term a "physiological fit," and our concern is with the harm that can arise from the fit mechanism. Fever is similarly a symptom of disease, yet pyrexial therapy has a definite value. The reports of brain lesions observed in animals after subjection to induced convulsions are of great importance, although many of the acute changes found could be temporary and reversible. No comparable reports on the human subject are available. Punctate haemorrhages were described in a recent paper (*Arch. Neurol. Psychiat.*, Chicago, **47**, 385) on changes in the brain after electrically induced convulsions in cats, but it was admitted that whether similar changes are to be expected in human beings treated with electric shock cannot be determined from the material investigated.

In the organic and idiopathic epilepsies there is no convincing evidence that recurring seizures always produce intellectual deterioration. There is, in fact, no correlation between the severity and frequency of the seizures and the mental condition of the patient. This rather suggests that deterioration in epileptics is due to factors other than the seizures. It is well known that many epileptics have normal or high intelligence and are well able to maintain their positions in the community.

The introduction of E.C.T. by Cerletti was based on animal experiments, which convinced him that no permanent brain damage was likely to ensue in the clinical application of his method, and it appears that nothing has since been reported which would justify the abolition of such a valuable therapeutic procedure. It produces an immediate remission in uncomplicated cases of mania and melancholia, as instanced by two of our patients who are now at home and have been leading useful lives for the past six months after five and six years of melancholic misery in the back wards of the hospital. The treatment is admittedly of less value in schizophrenia.

Dr. Hill refers me to your annotation (May 30, p. 674), which begins with the statement that the convulsive treatment of mental disease constitutes one of the most striking recent advances in therapeutics. I assume he agrees with this, although, judging from his letter, he appears not to have taken advantage of it yet.—I am, etc.,

West Riding Mental Hospital,
Wadsley

F. T. THORPE,
Acting Medical Superintendent.

Obituary

L. R. BRAITHWAITE, F.R.C.S.

Consulting Surgeon, Leeds General Infirmary

The Leeds School of Medicine loses one of its most brilliant sons in the death of Mr. Leonard Ralph Braithwaite, which took place at his home at Headingley, after a short illness, on December 18. Braithwaite was the pupil, the assistant, and the colleague of the late Lord Moynihan, and on him the mantle of the Moynihan tradition may be said to have fallen. His entire career was spent in the West Riding, although his reputation extended far beyond its borders. He did much by his skill as a surgeon, his wisdom as a teacher, and his kindliness as a friend and counsellor to enhance the fame of the Leeds school.

Braithwaite was born in Halifax in 1878. Entering the Leeds School of Medicine, he became one of the most distinguished students in the anatomical department. He graduated M.B., Ch.B., with first-class honours, in 1903. After serving as house-surgeon at Leeds General Infirmary, he was appointed resident surgical officer, and the manner in which he acquitted himself in that position ensured him a place on the honorary staff when opportunity occurred. He was appointed assistant surgeon in 1909, became a member of the full staff in 1924, and retired on reaching the age of sixty in 1938, when he was made honorary consulting surgeon. Together with his hospital appointment he held the chair of clinical surgery at the University, and was made emeritus professor on his retirement.

In 1910, shortly after his appointment to the staff of the Infirmary, he became assistant to the distinguished surgeon who was then known as Mr. Berkeley Moynihan, and the close association continued for fifteen years. Like Moynihan, Braithwaite chose abdominal surgery as his special province. He assisted his chief both in private practice at Park Square and at the hospital, and Moynihan testified on several occasions to his own good fortune in having Braithwaite, thirteen years his junior, at his right hand. He once wrote of him as "unsurpassed by any surgeon in this country for his power of dealing safely and in the most consummately skilful manner with any problem that an operation might present." On the occasion of his own retirement in 1925, Moynihan wrote to his colleague: "Throughout all these years I have had the greatest happiness in my association with you. . . . And your loyalty and good faith have been without blemish. I have counted from the earliest days on your being the best man in our school in your day." Braithwaite acquiesced fully in what might be called the Moynihan discipline. He regarded surgery as demanding not only knowledge and a skilled hand but the dedication of the whole of a man's powers, and he denied himself every indulgence or luxury which might cause the slightest departure from the physical and mental alertness necessary for a crucial task. The partnership between the two men was not interrupted even by war service, for when Moynihan went out to France, in the early part of the last war, Braithwaite accompanied him and afterwards worked with him in the hospitals of the Northern Command. He also served for a time with the Mediterranean Expeditionary Force in Salonika, and held the rank of major, R.A.M.C.

Much other work in Yorkshire included service on the honorary staffs of the Dewsbury and Pontefract Infirmaries and the Ilkley Coronation Hospital. He was an inspector of British Red Cross hospitals in the county. Like his old chief, he devoted much attention to the cancer problem. He was an active member of the British Empire Cancer Campaign, taking a great interest especially in the work done under the aegis of its Yorkshire Council in the department of pathology and cancer research of his own university. He was particularly skilful in the interpretation of scientific findings into language comprehended by the layman, and in the issue of propaganda containing the necessary warnings and instruction, but without emotional exaggeration. This faculty also accounted largely for his success as a teacher. He excelled alike in the formal lecture and in the practical demonstration. He wrote on surgical subjects, not extensively, but always with the same precision as characterized all his professional doings.

At the Royal College of Surgeons of England, of which he became a Fellow in 1907, he was elected a Member of Council in 1933 and held office as a Vice-President in the present year. He was Arris and Gale lecturer to the College in 1923, Moynihan lecturer in 1941, and Bradshaw lecturer a few weeks ago. He was a Fellow of the Association of Surgeons of Great Britain and Ireland, a prominent member of the Leeds and West Riding Medico-Chirurgical Society, and he had been for thirty years a member of the British Medical Association, and was vice-president of the Section of Surgery at the Annual Meeting at Belfast in 1937. Quite apart from his professional distinctions, he was greatly liked as a man, one who had hosts of friends among his colleagues, his students, and his patients, and with whom no time was grudged in the service of others and the solution of their difficulties. He was frequently an excellent host at the Leeds Conversation Club He was also a "hospital man" in the true sense of the word, playing a large part in the shaping of hospital policy in the city. His name and personality never obtruded themselves, and yet his influence was felt in all aspects of hospital work. He also did much of the preparatory work at the outbreak of the present war in organizing the Leeds General Infirmary to deal with possible civilian casualties on a large scale.

Surgeon Rear-Admiral G. GORDON-TAYLOR writes:

Leonard Braithwaite was trained in a great school of surgery at a time when the latter was perhaps at the very pinnacle of its fame, and he worthily maintained the prestige of the Leeds Royal Infirmary with all its wealth of tradition. In matters of surgical technique he was perhaps fortunate in his association with Moynihan, and in the flawless artistry of his own work and his gentleness of touch he even rivalled his master. Perhaps the most exquisite operation that I have ever witnessed by any surgeon in any country was a gastrojejunostomy performed by him at the Royal Infirmary a few years ago on the occasion of a visit of the surgical section of the Royal Society of Medicine to Leeds. As in the fingers of his master, the 5/8-circle intestinal needle was a beautiful tool in his skilful hands. Though possessed of sublime surgical courage, he was essentially a sure and safe surgeon; the desperate adventure and forlorn hope made less appeal to his artistic temperament than to those who are more frequently confronted with the cancer problem.

The memory remains of a charming English gentleman, proud of his Yorkshire county, devoted to the Leeds Royal Infirmary, a man of charm and blessed with a genius for friendship. In his cult of punctuality he was almost an ascetic; but the meticulous ordering of his days and his evenings was dictated by a supreme desire to give of his very best to those who entrusted their lives to his hands. His manner of speech with its attractive drawl did not betray his origin from a great Northern county; his personality radiated comfort and confidence and must have given courage to thousands of patients as surely as it enslaved his many friends and admirers. Best of all he loved his own hearth and home, his devoted wife, and the three daughters of an adored and adoring father.

Dr. GLADYS JULIA CUTHBERTSON RUSSELL, assistant M.O.H. for maternity and child welfare in Leeds, has died at the age of 46. She graduated M.B., Ch.B. of St. Andrews in 1919 and took the D.P.H. of Manchester in 1924. She joined the public health service after house appointments at the Dundee Royal Infirmary and the North Lonsdale Hospital, Barrow, working first under the Cheshire County Council and later in Monmouthshire. She moved to Leeds in 1928, and was soon promoted to take charge of the maternity and child welfare work of the city, and was personally responsible for the growth of the infant welfare clinics and ante-natal clinics, as well as for the development of the midwifery service and the introduction of the "home helps" system. The hospital accommodation for mothers and children was enlarged and reorganized, and Dr. Gladys Russell laid the foundation of the day nursery system. A public tribute to her admirable work and character has been paid by Dr. J. Johnstone Jervis, M.O.H. for Leeds, in the *Yorkshire Post.* She joined the B.M.A. in 1919, was an active member of the Medical Women's Federation, and the first medical woman to hold office as president of the Yorkshire Branch of the Society of Medical Officers of Health.

Dr. EDMUND HENRY COLBECK, who died suddenly at Farnborough, Hants, on Dec. 16, had practised for many years in Upper Berkeley Street, W., and on his retirement from the visiting staff of the City of London Hospital for Diseases of the Chest was elected emeritus physician. He was born at Batley in Yorkshire in 1865, and was educated at Tonbridge School, and at Nelson and Wellington Colleges, New Zealand; he entered Caius College, Cambridge, with a science exhibition, graduating B.A. with first-class honours in the Natural Sciences Tripos of 1887. He then went on to St. Mary's Hospital with a university scholarship, took his medical degrees at Cambridge in 1889, and proceeded M.D. in 1892. After serving as house-physician at St. Mary's and clinical assistant at the Vienna General Hospital, Dr. Colbeck took the M.R.C.P. in 1890 and was elected F.R.C.P. in 1904. During the last war he was consulting physician to the New Zealand Military Hospital at Walton-on-Thames and the South African Military Hospital at Richmond, holding the temporary rank of major N.Z.M.C. He was for a time additional examiner in medicine for the Cambridge Final M.B., and had been an active member of the British Medical Association, serving for two periods on the Council and holding office as vice-president of the Section of Pharmacology and Therapeutics in 1910. Two of his books—*Diseases of the Heart* and *The Science and Art of Prescribing*—passed into a second edition, and he contributed a number of papers to the medical journals on diseases of the heart and lungs. In 1937 a portrait of himself painted by Sir William Rothenstein was presented to Dr. Colbeck at the City of London Hospital for Diseases of the Chest to mark his retirement as senior physician after 45 years' service on the staff.

Correction

We regret that the date of the death of Mr. Russell Howard was wrongly given in the *Journal* of Dec. 19 (p. 740), as Dec. 4 instead of Dec. 2.

Medical Notes in Parliament

Venereal Disease: Regulation 33B

In the House of Commons on Dec. 15 Dr. EDITH SUMMERSKILL moved that an address should be presented to the King praying for the annulment of Regulation 33B. She said the regulation would be quite ineffective and would simply delay real action. During the last year the number of new cases of venereal disease coming to civilian clinics for treatment was 70,000. If they added those that had not been traced, the number of new cases might be 150,000. The numbers in the Forces must also be added, and we had, in fact, gone back in our figures to 1932. In a year or two we might go back to 1928 unless 16,000 expectant mothers who had been infected were traced. This regulation would not protect the men and the country from venereal disease. It provided for the treatment of individuals who had infected two others—nothing more. No two men would inform on a respectable woman who had been infected innocently. The regulation would get only a few people, probably only prostitutes and a few other unfortunate women, but the vast number of infected victims would be ignored. The problem called for a bold and courageous lead from the Minister. The time and money spent on propaganda could be more usefully directed if notification and treatment of these diseases were made compulsory.

Example of Sweden

It would be suggested that many members of the medical profession were not in favour of compulsion. Lord Horder, the president of the Society for the Prevention of Venereal Diseases, was 100% in favour, but she believed he had never been consulted. She drew attention to the speech of Dr. Laird at a meeting of the Medical Society for the Study of Venereal Diseases this year. He said that as a result of compulsory notification in Sweden the defaulter rate in 1935 was only 2.5%, but in this country, where we had not compulsion, it was 82.5%. Replying to Miss Rathbone, who asked if those figures had been checked, Dr. Summerskill said she could only quote figures given by responsible persons. Those figures were in the editorial in the *British Medical Journal* for Nov. 21 (p. 611), and the case was put for compulsory notification. Those who said that the results of compulsory treatment and voluntary treatment were the same had really no case if the figures were carefully examined.

There should, Dr. Summerskill continued, be clinics which were accessible and a social service which would follow up the contacts. There should also be a 100% grant from the Government. The clinics should not be labelled, but should be places where all women's complaints were treated. It was essential, as a wartime provision only, to have a blood test for all expectant mothers. We could profit by the experience of Sweden, where every person with venereal disease must submit to treatment. Immediately a patient reported to the doctor and his disease was diagnosed, the doctor reported to the medical officer of health. A person who exposed another to risk of infection was liable to imprisonment or a fine. If infection occurred there were even more severe penalties. Each party to a marriage must present a written declaration that he or she was free from venereal disease. If a patient ceased attending at a clinic an order would be served on him. If the order was ignored, he must undergo compulsory examination and treatment at the hospital. That would be a comprehensive scheme, and would bring home to every patient suffering from the disease that treatment was essential.

A Useful First Step

During the debate which followed Sir FRANCIS FREMANTLE expressed the opinion that the medical profession would be divided on this subect because they did not all approach it from the same point of view. The whole question to-day must be, What was going to be effective at present? The disease accounted for 15% of the admissions to mental hospitals in London and 16% of the stillbirths. Gonorrhoea, which was crippling rather than killing, accounted for half the sterility in women and 70% of the ophthalmia cases in newly born children. This was an international problem. Regulation 33B was a useful first step, and was all that could be done at present. What was the good of pretending to set up clinics when they had not the doctors to man them, and they could not get them while the war was on? The same thing applied to nurses, almoners, and health visitors. Notification without treatment was a waste of time and labour and brought the whole scheme into ridicule.

Dr. HADEN GUEST, supporting the regulation, said that in the Services, where there were both compulsory notification and compulsory treatment, there was a tremendous rise in venereal infection. Men and women in the Forces were suffering under tremendous strain—moral, spiritual, and physical. If, as he believed, Regulation 33B would help to protect them against the dangers of infection, it was the duty of Parliament to put it into operation. Compulsory general notification of tuberculosis had not been successful, and compulsory notification of venereal disease would not deal with the larger number of cases. They must get at the centres of infection, and the regulation was a way of doing that.

Widespread Ignorance

Sir E. GRAHAM-LITTLE supported the regulation as a first step. He urged that the way in which science should regard the curve of incidence of venereal diseases should be as an epidemic. It was useless to pretend that they could stop an epidemic by dilatory methods such as were proposed from time to time in the way of safeguards. It must be something that could be done here and now. The epidemicity of this trouble was one of its main features. There was widespread ignorance on the part of the general public as to the origin and the methods of the spread of venereal diseases. The compulsory treatment of infected people was a cardinal point of the value of the regulation, because, while a person was not cured of syphilis by one or two injections of the arsenical preparation now used so extensively, he or she was rendered very rapidly non-infective. He was not very fond of notification, which destroyed to a large extent the privacy which ought to attend medical treatment and might possibly defeat the end in view. He was not sure, however, that it might not become necessary for the Minister of Health to extend his powers to include notification—as he hoped he could—under the Defence of the Realm regulations.

Dr. H. B. MORGAN opposed compulsion in any form, whether it was notification or treatment. The idea of compulsion, he contended, was rampant in medical bureaucracy. A great danger was that some doctors were banding together in order to get people to do things which were really unnecessary and unjustifiable from the medical treatment point of view. There was a delusion among medical men that venereal disease was always curable. It was not. It could be cured in some cases. Sometimes patients resisted the most intense form of treatment. The Minister of Health should withdraw the regulation, provide adequate facilities for treatment, and do all he could voluntarily.

Minister's Reply

Mr. ERNEST BROWN, having emphasized that self-control was the proper course both medically and morally and that a higher ethical standard and a fuller appreciation of spiritual values were the only complete and final solution of the problem, said that unless something more was done in this country this might become a tragic issue. Most, though not all, of them agreed that they ought if possible to keep the voluntary system and make it effective. During the last six months they had taken steps to co-ordinate education on this matter with all other health subjects in the hands of the Central Council for Health Education. The Press had dealt with the subject most helpfully, and through arrangements with the B.B.C. information for the public was presented in a way it had never been presented before. A bold, constructive, and sane discussion of this matter on a healthy plane should help the religious forces of the country to make their own case clear. No Minister would raise this issue unless there were grave reasons for doing so, because it involved personal questions of the most intimate kind. As always in wartime there was a rise in venereal disease. The clock had been put back 10 years. The latest information was that the rise was still going on, and the clock was being put back still further. No one could be deaf to the fact that some regulation was needed. Regulation 33B was only a part of the answer to the question.

There were, Mr. Brown continued, three main essentials in the attack on these diseases—public education, adequate free treatment, and indirect action to discourage promiscuity. He put education first. The Ministry were arranging for a complete new series of posters for free issue to local authorities. In the Services educational work was very fully organized, and he had recently been in consultation with various civil Departments, especially on the production side, on the possibility of extending educational work in their activities, and here also expansion could be looked for.

Extent of Free Treatment

Free treatment under conditions of complete secrecy had been available for the last 25 years. There were now 249 treatment centres in Great Britain, three-quarters of which were at hospitals. Eighteen new centres had been provided since the war began, and five more were on the point of opening. The Service demands for specialists and other medical staff made it progressively less easy to start new centres, and to meet the need, especially in the rural areas, a new wartime arrangement had been initiated under which general practitioners with special experience provided free treatment at their own surgeries. The latest returns showed that 109 practitioners were taking part, and they served 74 areas in 11 different counties.

Indirect help by the provision of more and more healthy facilities for recreation was needed. The regulation was not an ill-judged attempt to solve the problem of venereal disease by a single measure but a carefully planned item in a planned programme. The Government claimed that it would stop a gap in the voluntary system which had existed for a long time, and which assumed a new seriousness in wartime. It represented a new approach to the problem—namely, a public health approach. It did not attempt to control solicitation, as did Regulation 40D of the last war, or to discriminate between the sexes. It provided the power to deal with a health problem in a manner which provided safeguards against blackmail.

Safeguards

Mr. Brown said he was proposing to issue a direction by which a patient would know of the penalties for deliberately making false statements before giving detailed information of any kind. A second safeguard was that the practitioner must be satisfied that the information given was *prima facie* reliable in the light of the medical evidence he had. The next stage was that the medical officer of health must receive two separate notices. That was put in the regulation as a safeguard. This was not the case in Sweden, where action could be taken on information received from one person, but here more than a double safeguard was given for persons concerned against any reasonable risk regarding false statements by asking for information to the medical officer of health from two different sources. He made it clear that the whole of the proceedings were private. There was no publicity unless the person concerned made the publicity. Moreover, every attempt would be made to get the person to come voluntarily.

Swedish Figures "Fallacious"

In conclusion, Mr. Brown said that the comparison between Sweden and this country in regard to persons defaulting before completion of treatment was completely fallacious. The Swedish figure of 2% was arrived at by comparing the number of persons who in 1935 ceased treatment early and could not be found again with the total number of cases notified. The English figure of 82% was obtained by subtracting from 100 the percentage of cases stated to have completed their tests of cure in 1935. It was clear that the figures were not comparable, and that the picture given by the English figure was quite misleading. The important percentage was the proportion of new infections with early syphilis which did not complete one course of treatment, since completion of one course even without any further treatment rendered the great majority of cases non-infectious.

Already the appearance of the regulation had caused some persons who had not volunteered for treatment before to come forward. He did not believe that the regulation would be ineffective, but if any new powers were needed he would not be slow to ask the House for them.

On a division, the motion to annul the regulation was negatived by 245 votes to 31.

Medical Attention of Home Guard

Answering Viscount Elibank in the House of Lords on Dec. 15, Lord CROFT said that if members of the Home Guard entered a civil hospital for treatment they would be treated as other civilian patients. If they entered a military hospital or convalescent home, it was desirable that they should be treated in wards or rooms specially reserved for them. The Government would give instructions for this procedure wherever possible in military hospitals. Members of the Home Guard were treated alike in sickness, and under conditions of battle or serious air raid it would often be impossible to segregate men according to rank except to the detriment of the medical attention they should receive. Provision was made that every Home Guard who was injured got medical attention.

Miniature X-ray Equipment

Miss HORSBRUGH stated on Dec. 15 that deliveries of miniature x-ray equipment had not begun. Progress had been made with the detailed arrangements for its use as soon as it came to hand. Mr. Brown hoped to issue in the next few days a circular to local authorities regarding the development of the tuberculosis service in all its aspects, including particulars of the allocation of the miniature x-ray sets. Arrangements had been made for additional beds to be available for tuberculosis. On the supply of nurses for this and other forms of work Mr. Bevin and Mr. Brown were discussing detailed plans with the organizations concerned.

Workmen's Compensation Bill

During the committee stage of the Workmen's Compensation Bill Dr. RUSSELL THOMAS said he understood that "pneumoconiosis" applied to the inhalation of any kind of harmful dust. "Silicosis" and "anthracosis" merely particularized the effect of the special dust inhaled. Anthracite workers quickly developed a cold, but did not get pneumoconiosis at once. The cough was caused by particles of coal irritating the bronchial tubes. The cough made the miner take deep breaths, whereby he inhaled spear-like particles of anthracite which pierced the lungs and set up fibrosis. Mr. PEAKE said the evidence was that this new form of pneumoconiosis existed among coal workers and coal trimmers in South Wales. It was therefore proposed to make a scheme which would cover these cases. There were now 43 diseases scheduled under the Act, and the Home Office would not proceed to make general schemes for pneumoconiosis affecting industry until there was evidence that the disease existed and that it was due to the employment. The Home Office had taken power to go ahead with further schemes without having again to come to Parliament for authority.

Mr. MARSHALL said he hoped that the scheme would be expanded to include pulmonary diseases which affected grinders. Mr. PEAKE stated that the Home Office would require specific evidence before schemes were made under the Bill. The word "pneumoconiosis" was widely defined to include silicosis, asbestosis, and any affection due to the inhalation of dust. Not in every industry where dust was inhaled could it be proved that inhalation caused a disease connected with the employment.

The Services

The King has approved that the following be mentioned in recognition of gallant and distinguished services in the Middle East during the period Nov., 1941, to April, 1942:

Major-Gen. D. C. Monro, late R.A.M.C., and Brig. (local) S. Smith, late R.A.M.C.; Brig. (temp.) F. G. A. Smyth, C.B.E. (since died), Brig. (local) N. St. J. G. D. Buxton, Col. (temp.) D. C. Scott, O.B.E., Lieut.-Col. F. R. H. Mollan, M.C., Major (temp. Lieut.-Cols.) D. Bluett, G. M. Heiron, A. G. Henderson, J. W. Hirst, T.D., R. Lees, R. Marnham, Major L. F. Richmond, Capts. (temp.-Majors) I. Aird, J. B. Bunting, J. M. Corall, J. G. Elmslie, R. S. Hooper, C. McT. Hopkins, R. J. Kellar, H. M. R. Knight, J. B. M. Milne, M.B.E., W. H. Purves, J. C. Reed, and Capts. R. D. I. Beggs, M.C., B. A. McL. Brown, J. W. A. Dennis, J. H. Gibson, J. D. P. Graham, D. R. Hood, C. R. Houghton, M.B.E., H. M. Kelsey, G. T. L. F. Morris, C. G. Pantin, W. J. Shannon, R.A.M.C.; Major (temp. Lieut.-Col.) B. D. Khurana, Major F. W. Whiteman, and Capt. I. B. Mallik, I.M.S.; Subadar-Major T. K. Afrida and Assistant Surgeon J. F. T. O. Nazareth, I.M.D.

The King has appointed Capt. S. A. Mian, I.M.S., an M.B.E. (Military Division), and has approved the mention of Col. A. C. L. O'S. Bilderbeck, Lieut.Col. G. B. Hanna, O.B.E., Capt. (temp. Major) K. L. Jetley, and Capt. P. J. Wormald, I.M.S., and Jemadars F. Singh and J. S. Dugal, I.M.D., in recognition of gallant and distinguished services in Waziristan.

Surg. Lieut.-Cmdr. (Acting Surg. Cmdr.) T. C. Stevenson, R.N.V.R., has been appointed O.B.E. (Military Division) for outstanding devotion to duty in tending sick and wounded during and after the fall of Singapore.

CASUALTIES IN THE MEDICAL SERVICES

Lieut.-Col. TREVOR AVELING BUTCHER, O.B.E., R.A.M.C., who was killed in action in North Africa in December, was born on Aug. 12, 1893, and was educated at the University of Cambridge and at University College Hospital, qualifying M.R.C.S., L.R.C.P. in 1918. He graduated M.B., B.Chir. in 1924, and proceeded M.D. in 1929. He served in the war of 1914-18, and in 1920 was appointed O.B.E. in recognition of distinguished and valuable services during the campaign in South Russia. After the war he was employed for a time at Ministry of Pensions hospitals at Grantham and Leicester, and then settled in practice in London. On the outbreak of the present war he re-entered the R.A.M.C. as lieut., was immediately promoted capt., became major in 1941, and lieut.-col. in 1942. He had been a member of the B.M.A. since 1927. H. R. writes: T. A. Butcher was a keen temporary R.A.M.C. officer with an excellent record in the last war. Not very long after demobilization he started practice in South Kensington, where his unassuming friendly personality soon made him popular with his colleagues, as well as bringing him a steady stream of patients. His quiet easy manner did not prevent recognition of the fact that he knew his medicine and surgery pretty thoroughly; and his capacity for steady reliable work and plenty of it naturally resulted in the reward of a growing practice. He was president of the Chelsea Clinical Society in 1937-8. He was also honorary local secretary for the Royal Medical Foundation of Epsom College. The sympathy of Butcher's many friends in Kensington will be universally extended to his widow and daughter.

Wounded.—Lieut. J. F. A. Wood, R.A.M.C.

Previously Reported Prisoner of War, now Reported Wounded and Prisoner of War.—War Subs. Capt. A. Macfarlane.

It is regretted that by a clerical oversight Major-General Harvey's surname was omitted from the obituary notice which appeared in this column on Dec. 26 (p. 770). The name should have read Major-General Alexander William Montgomery Harvey.

Two slips crept into the obituary notice of Capt. P. C. Banerjee in the *Journal* of July 11, 1942 (p. 56). He graduated M.B. of the University of Calcutta in 1918 (not 1932) and joined the B.M.A. in 1925 (not 1932).

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

The following candidates have been approved at the examination indicated:

FINAL M.B.—*Part I (Surgery, Midwifery, and Gynaecology)*: F Ashton, E. H Back, R. A J. Baily, H. W Balme, R. F. Barlow, D R. Barnes, C. H. Barnett, G. M. Barrett, W. M. Bennett, G G B. Blackman, R. H Boardman, J. F Bolton Carter, D. L Bridgewater, A. J. Briggs, W. L. Calnan A Carpenter, M. C. Connell, J. Davenport, E. W Deane, M B. Devas, R. J. Dickson, W. A. dos Santos, D. H. Drennan, C. O. Edwards, J. W. Evans J. W. Fawcett, W. M. Foreman, R. M. Forrester, H. A. Fraser, A. G Freeman, D. S. G. Genge, R. N. R Grant, H. C. Gupta, B Haigh, J R Handforth, E H Hare, H Harris, M. Hemming, J. ROYAL COLLEGE OF SURGEONS OF EDINBURGH

At a meeting of the Royal College of Surgeons of Edinburgh, held on Dec. 18, with Mr. J. W. Struthers, President, in the chair, the following, who had passed the requisite examinations, were admitted Fellows:

J. C. Brass, I. MacK. Davidson, A. T. George, A. M. Glen, J R. E. James, G. B. Jones, H. Karn, E. W Knowles, Jean Mason, J Potter, T C Skinner, K. Watson, H. G E. Williams.

No. 49

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Dec. 12.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Rate per 1,000 total births (including stillborn)			33					33		

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Includes paratyphoid A and B for Northern Ireland.

‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* 2,082 more cases of measles were reported than in the preceding week. Substantial rises were also recorded for whooping-cough 131, acute pneumonia 99, and diphtheria 68. There was a further fall in the incidence of scarlet fever 131, and of dysentery 58. One case of small-pox was notified in Yorks West Riding, Swinton U.D.

The only large variations in the incidence of scarlet fever within the counties were those of Staffordshire with 43 fewer cases, and Yorks West Riding with 41. Lancashire, with a rise of 51, was the only area with a notably higher incidence of acute pneumonia. The mounting notifications of whooping-cough were due mainly to the experience of Lancashire with 57 more, and Middlesex with 34 more cases.

A violent outbreak of diphtheria involving 111 persons in Edmonton M.B. brought the Middlesex notifications up from 19 to 126. In Yorks West Riding the previous total went up by 33 and in Staffordshire by 26; in Lancashire there were 41 and in Wales 36 fewer cases.

The largest increases in the notifications of measles were those of Lancashire 507; Yorks West Riding 420; Nottinghamshire 198; Leicestershire 183; Staffordshire 147. Lancashire and Yorks West Riding contributed 44% of the total cases of measles during the week. There were severe epidemics in some of the county boroughs, the biggest totals this week being reached by Manchester C.B. 449, Bradford C.B. 495, and Leeds C.B. 487.

Although the figure for dysentery has fallen by 58, the disease is still prevalent: 14 cases, an increase of 11, were recorded in Hampshire (Petersfield U.D. 2, Petersfield R.D. 12); in London 18 cases were recorded in twelve boroughs; in Lancashire notifications went up from 32 to 34 (Liverpool C.B. 14, Manchester C.B. 8, Blackburn R.D. 5, Whiston R.D. 6); and in Yorks North Riding from 10 to 17 (Middlesbrough C.B. 12, Redcar M.B. 5).

In *Scotland* there were 75 more cases of scarlet fever, 51 more of acute primary pneumonia, 40 more of measles, and 31 more of diphtheria. The higher incidence of diphtheria and pneumonia was fairly general. Dundee with 104 notifications had the largest number of cases of measles; in Glasgow the figure had risen from 46 to 82, and in Aberdeen from 35 to 63. Of the total cases of scarlet fever 40% were reported from the two cities of Glasgow 99, and Edinburgh 87.

Up to Dec. 22 there were 35 cases of small-pox, with 8 deaths, in Edinburgh. No further cases have been reported from Lochaber, Inverness-shire, where the only case proved fatal.

In *Eire* an increase of scarlet fever, due to an outbreak in Waterford C.B. 33 cases, was the chief feature of the returns. The notifications of poliomyelitis fell from 18 to 12.

TUBERCULOSIS IN WARTIME

Speaking on the subject of tuberculosis in peace and war in his Malcolm Morris Memorial Lecture recently, Sir Arthur MacNalty said that in 1938 all forms of tuberculosis were declining in Great Britain. The decline in mortality rates had been greater since 1931 than at any time during the present century. It was, therefore, bitter to record that progress had for the second time this century been retarded by war. In 1939 deaths from tuberculosis in England and Wales numbered 26,250, in 1940 28,144, and in 1941 they had risen to 28,669. The figures for the two complete war years did not include non-civilians, but there was some increase in the disease among members of the Services. The incidence of pulmonary tuberculosis in the Army had shown, so far as men were concerned, no upward trend. At the outbreak of war there was a temporary dislocation of the tuberculosis services in some areas, but excellent work was now being done in spite of many difficulties. The present scale of rationed food was adequate for the tuberculous if the diet was carefully planned, as in sanatoria and hospitals. Since the war there had been an increase in mortality from this disease in mental hospitals and mental deficiency institutions. Miniature or indirect radiography, the speaker continued, was an important aid to early diagnosis, but it reinforced and did not supplant clinical examination. Recent work in chemotherapy encouraged the hope that a drug might be found which would destroy the tubercle bacillus in man. After the war more institutional provision and beds would be needed. The Medical Research Council favoured the setting-up of a national board to co-ordinate the planning of a national rehabilitation scheme. This was first advocated by Sir Pendrill Varrier-Jones in 1936. Such a board was called for, especially at the present time.

Medical News

A conference for workers in the medical sciences will be held on Saturday, Jan. 9, at 2.15 p.m. at the London School of Hygiene, Keppel Street, W.C.1. The conference will consider problems connected with the organization, application, and personnel of the medical sciences. It is hoped that any persons interested will attend, and will bring forward their own experience and suggestions for problems to be undertaken. Programme: (1) Address by the Chairman (Dr. D. McClean); (2) address by the industrial organizer of the Association of Scientific Workers on the part which the association can play in improving the status of medical scientists and in bringing the results of their work before the public; (3) accounts by members of the Medical Sciences Committee of the work of the subcommittees: Medicine in industry—Dr. D'Arcy Hart, Nutritional research and the need for a Nutrition Council—Dr. Yudkin, Co-ordination of medical research—Dr. Oakley, Training of medical technicians—Mr. Griffin, The need for a national supply of experimental animals—Mr. Bacharach. Further information may be obtained from the A. Sc. W., 73, High Holborn, W.C.1, or from Dr. J. H. Humphrey, 81, Highgate West Hill, N.6.

The London and Home Counties Branch of the Medical Superintendents' Society will hold a meeting on Saturday, Jan. 16, at 2.30 p.m., at B.M.A. House, Tavistock Square, for a discussion on the relative merits of medical and lay administration of hospitals. Any medical man who is interested will be welcome at the meeting.

It is stated in the Press that Dr. John Ryle is to vacate the regius professorship of physic at Cambridge during the present academic year.

Dr. John Crosthwaite Bridge has just retired from the post of Senior Medical Inspector of Factories, to which he was appointed in 1927; he will be succeeded by Dr. E. R. A. Merewether, who is now in the United States lecturing at the invitation of the American Public Health Association.

Dr. R. E. Smith, medical adviser to Rugby School, has been appointed health adviser to the National Association of Boys' Clubs. Dr. Smith's appointment is a direct outcome of a memorandum submitted to the Council of the National Association by Sir Hubert Llewellyn Smith, and it is hoped that, as well as advising on health problems, Dr. Smith will undertake research work concerning the general health of the working boy.

The Registrar of the University of Glasgow and the Secretary of the University of Edinburgh have jointly published an announcement that under recently revised regulations of the Ministry of Labour and National Service it will be necessary for all young men who wish to enter upon the study of medicine at either university in Oct., 1943, and who were born on or before July 31, 1925, to make immediate application on a form to be obtained from the Registrar of the University, Glasgow, W.2, or the Dean of the Faculty of Medicine, the University, Edinburgh, respectively. Women applicants and men born after July 31, 1925, should not apply until May 15 next.

Plans for building hospitals, clinics, maternity and child welfare centres, where needed, from factory-produced units have been developed by the British Concrete Federation in collaboration with the Ministry of Works and Buildings. These units can be expanded or adapted to suit requirements, and a unit building is proof against fire and the one-kilo incendiary bomb, has a high resistance to blast, and can be erected with the minimum of skilled man-power. Among units shown recently in London were a hospital for 36 patients but capable of expansion, an operating theatre and radiography unit, and clinics and hygiene centres for rural districts.

The Shipwrecked Fishermen and Mariners' Royal Benevolent Society, which lately celebrated its centenary, was founded by John Rye, a philanthropic medical man of Bath, and C. C. Jones, an ex-pilot of Bristol. A feature of this society is that it obtains its funds not only from charitable donations and subscriptions, but also from contributions by seamen themselves.

In accidents other than those on the roads and in industry 8,000 people lose their lives annually, and in a recent analysis of 1,153 of these over half were due to falls, but only a small proportion to falls in the black-out. Nearly one-fifth were due to burns (30% in children) and scalds (80% in children) and one-tenth to drowning. The Royal Society for the Prevention of Accidents prepared this analysis.

Examination of the weight of Paris school children for the school year 1941–2 has shown that an average of 15 to 20% of the children have undergone a loss of weight or no change, whereas in normal times this occurs in less than 1%. The average increase in weight was also distinctly less than in the years before 1939.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be sent to the Secretary.

TELEPHONE No.—B.M.A. and *B.M J.*: EUSTON 2111.

TELEGRAPHIC ADDRESSES.—EDITOR, *Aitiology Westcent, London;* SECRETARY, *Medisecra Westcent, London.*

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

QUERIES AND ANSWERS

Dressing for Cancer of Breast

Mr. WALTER PHILLIPS, F.R.C.S., writes: In reply to "Deodar" (Nov. 28, p. 654), in my experience the following method has given satisfaction for inoperable fungating carcinomas. Prepare a solution of 10% formaldehyde in water—about 1/3 of the official liquor. Cut a pad of two or three layers of lint to fit the ulcer. Smear zinc ointment over the surrounding skin for protection against caustic action of formalin. Soak the pad in the formalin solution and apply to the ulcer, tucking in the edges so as to avoid overlapping skin margins. Cover pad with a slightly larger piece of jaconet or other waterproof material, cotton-wool, and bandage. Retain in position for 24 to 48 hours. It may be necessary to give a sedative if pain results. A dry necrosis of the fungating mass is produced with resulting cessation of discharge. This horny material may be painlessly pared away with a scalpel until blood appears. The formalin may then be reapplied until the skin shows signs of reaction. Any dry dressing may be used after. The whole process can be repeated in three weeks to a month as necessary. The economy in dressings is remarkable.

Radium and Radon Burns

Dr. IRWIN MOORE (30A, Wimpole Street, Cavendish Square, W.1) asks that anyone who has had practical experience of the after-effects and treatment of serious radium or radon burns in the gynaecological and rectal regions will communicate immediately with him.

Income Tax

Payment of Bank Interest

"Z. X." left his private practice at the outbreak of war and has worked under the E.M.S. ever since. How can he now obtain relief for the bank interest he continues to pay?

⁂ As he is not carrying on a practice he cannot regard the bank interest as a professional expense; but he is entitled to an allowance, either by set-off from the tax now assessed under Schedule E or by way of repayment. He should obtain a certificate from his bank showing what interest he has paid for the period from the ending date of his last professional account to April 5, 1942—distinguishing between the financial years concerned—and forward it to the inspector of taxes asking him to arrange for the appropriate repayment or set-off.

Remittances by Officer Abroad

"CAPTAIN" is a British officer serving in India. He is paid £200 a year as a director of an English company, which is taxed at 10s in the £, less the 10% for earned income relief. He remits £32 10s. a month to his wife in the United Kingdom.

⁂ Assuming that the remittances are made from earned income, and not from dividends, etc., from foreign investments or property, the amount is *not* liable to income tax in this country. As regards the £200 from the directorship the position is a little complicated, he is entitled to such an adjustment as will leave him in the position of having paid United Kingdom income tax in the proportion which his total real income bears to his United Kingdom income. For example, if his pay, etc. (not liable to income tax here), is, say, £600, and the amount of tax which would be payable here on an earned income of (£200+£600=) £800 is £x, then the tax ultimately payable will be 200/600 of £x. A claim to adjustment should be made to the Board of Inland Revenue, Somerset House, London, W.C.2. Any capital brought home after the war in so far as it results from savings of earned income will not be liable to United Kingdom tax.

Absentee Practitioner—Earned Income

"CAPT, R.A.M.C.," is an absentee practitioner whose practice is being carried on under the Protection of Practices Scheme. His half-share has been assessed as unearned income.

⁂ As we understand the position such income is regarded as accruing from the continued exercise of the taxpayer's profession, and as such we consider it should be assessed as earned income, even if the practitioner is not able to show that he has assisted occasionally in the conduct of the practice during the financial year in question. If the local inspector of taxes will not agree to amend the assessment we suggest that our correspondent should put the facts in writing to the Chief Inspector of Taxes, Imperial Hotel, Llandudno, N. Wales.

Appointment: Motor-car Expenses

"P. Q. R." points out that retired medical men who take up work—e.g., on medical boards, the emoluments of which are charged under Schedule E—are at a disadvantage in that they are not allowed to deduct the expense incurred in keeping a car to travel to and from the place where their work is done.

⁂ This is so. The rule relating to Schedule E as interpreted in the courts prevents the deduction of the cost of travelling from the place of residence to the place where the work is done, the grounds of the judicial decision being that such expenses are not incurred "*in* carrying out the duties of the office."

Reduction in Earned Income

C. J. M. points out that the operation of the previous year's basis of assessment where, owing to some change in circumstances, the income has declined, involves the taxpayer either in unfair taxation or in the trouble, and probably the expense, of producing accounts and claiming an adjustment.

⁂ We agree that the "relief" from the operation of the previous year's basis when the income falls by 20% does involve some trouble, but it is only natural that the Revenue should require evidence that the relief is due. If the practitioner returns to his practice after the war, he stands to gain by the way in which the previous year's basis will work and, unlike himself, the Revenue has no right to claim a departure from it.

LETTERS, NOTES, ETC.

Recurrent Chicken-pox?

Mr. FRANK MANNINGTON (London, N.10) writes: On Oct. 21 last I saw a child, aged 7, with a typical but mild attack of chicken-pox. This followed a normal course and the child returned to school at the end of three weeks. On Nov. 25 I was again called to see her and found her suffering with a severe attack of chicken-pox, which again is following a normal course. During over 40 years of practice I have never before seen a recurrent attack of chicken-pox. Perhaps it is worth putting on record.

Health of the Medical Student

Dr. B. H. SHAW (St. Mawes) writes: I have read Dr. Hope Gosse's article (Nov. 14, p. 567) on the health of the doctor. May I suggest that attention should be given to the health of our medical students at the present time. The diet of students in college is carefully attended to and adequate, but the majority of those who are "taking out" hospitals are away from home and left to the mercies of landladies, no extras are allowed, and young, growing, hard-working adolescents have exactly the same rations as old people. It is obvious that the strain and mental tension involved at the present time in intensive application are very considerably greater than in peacetime, as the standard of the examinations must be maintained and apprehension of failure to sensitive natures under the present circumstances is a most serious matter. There is no excuse whatever for failure to see that the nutrition of these young people, compelled to undergo such severe conditions, should not be at least as good as that of other adolescents engaged in work of national importance. If it is to be understood that medical students, being in a reserved occupation, are so engaged, it is manifestly the duty of the authorities concerned to see that adequate food for their needs is provided, especially proteins, and not just enough to keep body and soul alive. When breakdowns occur a very heavy responsibility is incurred.

A "Medical Protection" Jubilee

It is just 50 years since the London and Counties Medical Protection Society came into existence. At the end of its first year it had 200 members, compared with the 18,000 it has now. Its first annual report, with the subheading "A Year's Work among the Black Sheep," is an amusing and even flippant document. In 1892 there were "specialists in corpulency," charlatans whose practice it was to circularize fashionable dressmakers in the hope that the latter would bring their slimming cures to the notice of clients. The report also mentions a man who—in the hard-headed Midlands too, not in the gullible South—succeeded in passing himself off as a doctor on the sole ground of the possession of a high gig and a smart footman. Medical practice changes, and with the change come new pitfalls. When the Society began its work there were no complaints over such matters as burns arising out of electrical treatment or failure to make an *x*-ray examination in a suspected fracture. Indeed, some of the earliest cases it had to defend turned on the point that the practitioner had done too much rather than too little. It is remarkable that in its 50 years the Society has had only four Presidents—Sir Jonathan Hutchinson, Dr. G. A. Heron, Sir John Rose Bradford, and now Sir Cuthbert Wallace, who was re-elected to that office at the annual meeting the other day. During the past year it has had to deal with 886 applications for advice and assistance. The idea has arisen in some quarters that a doctor in an official position or in the Services does not require protection, but only recently the Society has been concerned to defend practitioners in the employment of local authorities and officers tried by court martial The Treasurer, Mr. W. M. Mollison, reports a prosperous state of affairs, with over £85,000 accumulated funds. Originally the Society was responsible only for the payment of a member's own costs in proceedings, and in the event of an adverse verdict the member had to pay any costs or damages on the other side, but since 1924 it has given an unlimited indemnity.

Diet and Queening

Queen bees and workers are produced from identical larvae, and it is possible to rear queens from any female larva less than 3 days old by providing it with the appropriate food. On the chessboard a pawn has to plod dangerously to the eighth square to become a queen; but among bees royalty is a gastronomic affair. During the first two days after hatching, royal jelly, which is a secretion of the pharyngeal glands of the workers, is given to all female larvae. On the third day the diet of the larvae destined to become workers is abruptly changed, while the larvae destined for the throne continue to receive royal jelly. Heyl (*Science*, 1939, **89**, 540), it may be remembered, demonstrated the gonadotrophic activity of royal jelly on the ovaries of the immature rat. The jelly has been analysed by various workers, and at one time it was thought that the magical property resided in vitamin E. P. B. Pearson and C. J. Burgin (*Proc. Soc. exp. Biol.*, N.Y., 1941, **48**, 415) have recently come to the conclusion that the only vitamin in which royal jelly is unusually rich is pantothenic acid. It is, in fact, the richest known source of this member of the vitamin B_2 complex, but it has yet to be proved that it is pantothenic acid which will turn a possible worker into an actual queen.

Soluseptasine in Rheumatoid Arthritis

Dr. BERNARD F. SHEA (Sligo) writes: I have treated many cases of early rheumatoid arthritis with injections of soluseptasine, and the results have been so satisfactory that I think a more extended trial is worthy of consideration. My first case was in a married woman of 24 who had swollen ankles and great pain and limitation of movement in her knees, elbows, and shoulders. She had also typical swelling of the joints of the fingers. She had been in this state for three years and could walk only with great difficulty I gave her 12 injections of 10 c.cm. of 10% soluseptasine intramuscularly daily, and improvement set in immediately. She is now, 2 years afterwards, quite well. I have treated many more cases with like results, and even chronic cases improve with these injections. I have sometimes given 18 injections to a severe case and have never found any toxic reactions in a series of 50 cases.

Rationed Distribution of Doctors?

Dr DUNCAN LEYS writes with reference to his letter published on Dec. 12 (p. 708): I am reminded that the public health and medical staff of Inverness and its environs (with a population which I estimated at 30,000) also serve the county of Inverness with a further 55,000 people, so that the present staff is less, not more, than my estimated number required for basic essential wartime needs in a rationalized medical service.

Unreliable Vaginal Pessaries

Dr. MARIE C. STOPES writes. May I support emphatically the letter you publish from Dr. Lilias M. Blackett Jeffries (Dec. 12, p. 714) saying that quinine pessaries are widely advertised and the public "has complete confidence in them" though they lead to many undesired pregnancies. The misplaced confidence of the public is partly created by members of the medical profession who unfortunately advise their use, but even more by Press advertising. Since the foundation of the first birth control clinic we have done everything possible to spread the truth—namely, that *no* medicated pessary is, or can be, 100% safe by itself.

BRITISH MEDICAL JOURNAL

LONDON SATURDAY JANUARY 9 1943

THE PREMATURE INFANT: MANAGEMENT AND PROGNOSIS

BY

W. R. F. COLLIS, M.D., F.R.C.P., F.R.C.P.I., D.P.H.
Physician to the National Children's Hospital; Paediatrician to the Rotunda Hospital

AND

M. A. MAJEKODUNMI, M.D., D.C.H., L.M.
Assistant to the Paediatric Department, Rotunda Hospital

There has been widespread discussion, with grave disagreement, between observers in various countries concerning the correct definition of prematurity. The obstetrical conception of prematurity is inacceptable from the paediatric point of view, because the dates given by pregnant women are notoriously inaccurate. Also, debilitating diseases in the mother have such a profound influence on the birth weight and vitality of the infant that a baby born under such conditions, even when it reaches term or sometimes goes past it, must be regarded as immature, as it tends to be under-developed and incapable of carrying on independent extra-uterine existence without special measures to help it.

The definition of prematurity now widely accepted is that recommended by the International Committee at Geneva in 1937, and agreed to by the British Paediatric Association in 1938; this gave the higher limit of viable prematurity as a birth weight of 5½ lb. and the lower limit as the 28th week of pregnancy, irrespective of the weight at birth. This standard has been found satisfactory in the Rotunda Hospital, where a special department has recently been established for the management of premature and weakly infants.

We are of the opinion that the question of the premature infant has not received the attention it deserves from the medical profession in general. A study of the public health reports of most of the thickly populated areas of Great Britain and Ireland reveals a considerable reduction in the infant mortality rate during the past ten years—i.e., from about 100 to 60 per 1,000 births. On the other hand there has been no appreciable reduction in the neonatal death rate, which still remains at about 32. This means that 50% of the infant mortality during the first year of life occurs within the first month. For a more detailed analysis of the neonatal death rate one must turn to the maternity hospital reports. The latest report of the Rotunda Hospital records 39 neonatal deaths from a total of 3,194 live births; of these 39 infants 25 (60%) were premature. In the National Maternity Hospital, Dublin, out of a total of 133 neonatal deaths 67 (50%) occurred among premature infants; and in the Royal Edinburgh Maternity Hospital in 1938 the proportion was over 50%. These figures show that the greatest single cause of death in the neonatal period is prematurity. Hence, if any appreciable reduction is to be made in neonatal mortality attention must be focused upon the management of premature infants and the causes of their death.

The Outlook for the Premature Infant

Before advocating the difficult and expensive measures necessary, however, it is wise to find out whether the saving of this group of infants is biologically sound. Opinions certainly differ as to the outlook for the premature infant. Capper (1928) maintains that it as often as not becomes the backward school child or a candidate for a home for imbeciles. On the other hand Wallich and Fruhinsholz (J. H. Hess, 1923) record that Newton, Rousseau, Voltaire, Couvier, Victor Hugo, Lamartine, and Renan were all premature-born. As late as Dec., 1940, we find Robert Hutchison, then President of the Royal College of Physicians and ex-President of the British Paediatric Association, when writing of premature babies saying: "I have a strong suspicion that, of those who survive, a large proportion turn out defective, either physically or mentally, or both."

To help to clear up the matter we have recently made a follow-up study of a group of premature infants which had passed through the paediatric department of the Rotunda Hospital within the last seven years. We were able to trace 45 of these. Seven had died—two within the first month of discharge from hospital, four during the first year, and one at the age of 2 years from bronchopneumonia following an attack of measles. The death rate in this group is only slightly higher than the infant mortality rate in the city of Dublin as a whole.

Of the 38 survivors nine can be said to have some slight abnormality—e.g., three of the children, all of whom are under 5 years of age, have not yet learnt to control the bladder. We feel confident, however, that they will eventually overcome this handicap, as some of the 7-year-olds whom we examined did not learn bladder control until they were 6 years of age. Four of the children have some speech defect (three stutter slightly and one has idioglossia). Those also, we believe, will overcome their handicap if carefully trained during development. One of the remainder has a right-sided hemiplegia: the right hand shows a choreiform movement together with a typical dinner-fork deformity. The lesion in this case would appear to be in the region of the basal ganglia. The child is at present 7 years old, and is able to walk almost perfectly in her special boots. Briefly, the clinical history is as follows:

Weight at birth: 4 lb. 13 oz.
How much premature. 6 weeks
Place in family: 8th
Mother's health in pregnancy: Severe albuminuria
Remarks: Baby very jaundiced at birth; was treated for icterus gravis

The other has Little's diplegia; this is an only child, and her mother is very intelligent and co-operative. Through her patient training the child has now learned to walk, and continues to progress as well as might be expected. She is now 3 years old. A brief summary of her hospital chart shows the following:

Weight at birth: 3 lb. 1 oz.
Nature of labour. Rather difficult delivery with version and manipulations
How much premature: 9 weeks
Place in family: 1st
Remarks. Crown of head appeared bruised. Child was 10 weeks in hospital, and was discharged weighing 6 lb. 3 oz

To sum up, we found that out of the 38 surviving children 29 (76%) were perfectly developed and equal in weight and height to the average full-term infant for their age; of the remaining 9 only two were found to have severe defects, and in neither case could the result be attributed to their prematurity. The series is small, but we are justified in allowing these figures to support our previous belief, founded upon individual observation, that premature infants, if without congenital stigmata and given special care, will generally grow up normally.

The Rotunda Paediatric Department

Some 15 years ago the Rotunda Hospital contained no paediatric department, intern or extern. There were no temperature charts for babies, and few notes were kept regarding their progress. It is stated that some 60% of all premature and sickly babies born in the hospital died before discharge. A paediatric department was then founded, and has since gradually developed into the following organization. Special nurseries with 31 cots have been set aside for the management of all premature infants and those suffering from other neonatal disorders. These nurseries are under the control of a paediatrician and managed by a paediatrically trained nursing staff. The normal babies are still managed in the general puerperal wards with their mothers, though each baby now has its own chart, on which its daily weight and temperatures, together with other clinical observations, are noted. A large extern clinic for babies born in the hospital or in its district has also been instituted. The method in the Rotunda Hospital differs from that in some other well-known maternity hospitals in the way normal and abnormal babies are managed in different departments. It has been adopted for two reasons. First, if a sister is given charge of all infants, normal and abnormal, the latter do not receive the same attention as if she has all her time to concentrate on them. Secondly, by leaving the normal babies with their mothers and their midwives in the wards both the latter are taught to manage the babies by ordinary simple methods which can be carried on in the home. It must be admitted that this exposes the normal babies to some degree of infection from visitors; but we believe the system is in accordance with the movement of medical opinion, for we visualize a time when every mother going into a maternity hospital will be provided by society with a room, or at least a cubicle, for herself and her baby during the few days she must spend within its walls. This will entail some modification of present arrangements in the puerperal wards, but the necessity for a nursery for the special cases will still exist.

The result of these measures is seen in the last report of the Rotunda Hospital, quoted above, the premature death rate having fallen from 60% to the present figure of 16%. The measures which are responsible for this very large reduction are discussed below under four headings: (1) maintenance of body temperature; (2) feeding; (3) nursing technique; (4) prevention of infection.

Body Temperature

In the premature infant the heat-regulating mechanism is imperfectly developed at the time of birth, and unless the infant is kept warm by the application of external heat the body temperature quickly falls. This inability to regulate and to maintain a normal body temperature is attributed to incomplete balance between loss and production of heat. The premature infant, if left unattended, rapidly cools down to the temperature of the surrounding air, and among the factors which favour such a rapid lowering of the body temperature are: (*a*) the relatively great area of heat-eliminating surface—i.e., the skin as compared with body weight; (*b*) the absence of subcutaneous fat, which increases the escape of heat from the body (Blackfan and Yaglou, 1933); (*c*) the very low production of heat; and (*d*) the failure to increase this by crying, kicking, and other activities when the environmental temperature falls below normal.

On the other hand, hyperthermia is very easily induced in these infants, as the heat-eliminating mechanism is equally imperfectly developed: the sweat glands do not function as freely as in full-term infants, and sometimes they fail to act at all. Incubators are now available for the maintenance of body temperature in premature infants; some modern ones are so constructed that the temperature and humidity of the air are automatically adjusted, and the infant can be fed, weighed, and the diapers changed without removing it from the incubator. Incubators are, however, very expensive, and in our opinion are too complicated for use in an institution that has a large number of infants to look after.

When one is confronted with the problem of a premature infant in the environment usually met with in practice the quickest and cheapest way to maintain its body temperature is by the use of three hot-water bottles suitably covered with blankets or flannels, one being placed on each side of the infant and the third at the feet. The water is changed in rotation every few hours. In more favourable circumstances electric pads or electrically heated blankets may be used with advantage, provided they are closely watched to prevent overheating. For hospital purposes or in nursing homes some form of heated cot is most efficacious. In the Rotunda Hospital a simple incubator cot is used, which consists of a rectangular wooden box, divided into an upper and a lower compartment by a removable "mattress" formed of zinc strips criss-crossed on an oak frame. In the lower compartment are fitted two high-resistance electric bulbs, which keep the temperature of the cot between 80 and 85° F. The upper compartment, well cushioned, receives the infant. This incubator cot is a modification by one of us (W. R. F. C.) of the type introduced by Allen of Belfast.

In addition to the use of the heated cot the temperature of the ward is maintained at 70 to 75° F. by central heating. Such a high temperature tends to dry the air, and premature infants do not thrive in a low relative humidity. To combat this difficulty a humidifier which keeps the relative humidity of the ward between 60 and 65% has been installed in the premature ward. Conditioned air is of course the ideal, but for financial reasons we have not yet been able to install the apparatus in the Rotunda nurseries. All infants weighing less than 5 lb. at birth are nursed in this specially heated ward of high relative humidity. When they are 5 lb. in weight they are transferred to a cooler ward with a temperature of 60 to 65° F. and a relative humidity of from 40 to 45%. It has been our experience that larger premature infants of 5 to 5½ lb. do not gain weight as readily when nursed in the heated and humid ward as when kept in the cool ward. In the private house the relative humidity can be maintained by the use of a steam kettle or by spraying the room frequently with warm water, or, if the floor material is suitable, by mopping the latter with a wet towel. The premature infant becomes dehydrated if the relative humidity of the room is allowed to fall below 30%, and this very quickly takes place if electric heaters are used in a badly ventilated room.

The use of suprarenal cortical hormone (both synthetic and/or the extract of the gland cortex) for the treatment of dehydration and for stimulating growth in premature infants has recently been reported upon favourably by some observers. We have used this substance in some cases, both to treat dehydration and to prevent it, but we have not found it of general benefit. It has proved of great value, however, in some cases of birth shock and in certain cases of dehydration, possibly those associated with a ketosis.

In spite of the use of the heated cots for external application of heat the temperature of premature infants fluctuates considerably in the first few days of life, and some of them cool down to an alarming degree within half an hour of birth. It is often very difficult to restore the temperature to normal by employment of the incubator cot alone, so recourse has to be had to some means of stimulating the infant's production of heat. The method we now use as a routine at the Rotunda Hospital is the administration of thyroid, which has proved most successful. The infant is given 1/4 gr. of thyroid (B & W) on admission, and 1/10 gr. twice daily for the next three to four weeks. We have found this hormone extremely useful in maintaining the body temperature and stimulating growth in premature infants.

Feeding

The digestive apparatus, even in the smallest premature infant, is reasonably well developed: most of the digestive ferments are present as early as the fourth foetal month, increasing gradually until the adult level is reached when the baby is 3 months old (Hess, 1923). The ideal food is breast milk, and every effort should be made to secure this. The mothers of such infants seldom, however, have enough milk until about the third or fourth day. In such circumstances, if possible, pooled breast milk should be obtained or a wet-nurse be engaged. In a great many cases it will be found impossible to obtain an adequate supply of breast milk, and artificial feeding will have to be resorted to.

At the Rotunda Hospital the smaller premature infants are usually fed two-hourly by day and three-hourly by night, making a total of ten feeds in the twenty-four hours; the larger infants are fed three-hourly. Immediately on admission to the nursery the infants are given water 1/2 oz., glucose 1/2 drachm, and thyroid gr. 1/4. Feeding is started two hours later, except in the case of cyanosed infants and infants born of toxaemic mothers, who are kept on glucose-water for the first 12 hours. For the first three or four feeds the infants are given a weak mixture of milk and water (e.g., 1 part of milk and 2 parts of water), gradually increasing to a stronger mixture in two to three days. Breast milk is used when available, and by the end of the first week the infants are able to take this undiluted. When breast milk is not available, however, humanized dried milk or peptonized milk is substituted: these preparations are almost impossible to obtain at present, and we are now using half-cream "Cow & Gate," dried acid milk, or boiled cows' milk with equal success. Because of the low food value of weak milk mixtures they have to be reinforced by the addition of sugar (1 drachm to 2 oz. of the mixture). It is well known that premature infants take sugar with avidity during the early days of life, and it has been suggested that hypoglycaemia may be the cause of death in some of them, especially those weighing less than 3 lb. at birth. We have found, however, that they do not tolerate such a high percentage of sugar after two or three weeks, and the earliest clinical indication of carbohydrate intolerance is when the buttocks tend to get red. When this occurs sugar is cut down to about 1 drachm in 3 oz. of the mixture, and the protein content is correspondingly increased: this increase must, however, be very gradual, otherwise the infant will develop protein dyspepsia and start vomiting curds.

Our experience has been that infants weighing less than 4 lb. at birth or who have had a difficult delivery are seldom capable of sucking from the breast, and even when the milk is expressed are too weak to obtain an adequate supply from the bottle. Special teats, Breck feeders, pipettes, and spoon-feeding have been recommended for such infants; but these methods are unsatisfactory, as the feed tends to get into the larynx, causing coughing and choking. We now use gavage (tube feeding) for babies who are unable to suck easily. The pharyngeal reflex is imperfectly developed in these infants, so that the operation is carried out with the minimum of disturbance while they lie in their cots. When the infant starts to suck at the tube it is a sign that bottle-feeding may be gradually started. By this means we are able to avoid giving concentrated mixtures as advocated by some workers: these in our opinion are a potent cause of digestive disturbances. Instead of thickened feeds we give more feeds in the twenty-four hours—i.e., about 10 oz. to babies weighing 3 lb. or less, and about 15 oz. to babies over 4 lb. It is our experience that at this period of life the quantity of feeds is more important than the quality. By giving large quantities of fluid, in addition to keeping the infants in an optimum air condition, we have been able to reduce the initial weight loss to a considerable degree, and in some cases to eliminate it.

We have found it impossible to make an invariable rule for supplying the calorie requirements of our premature infants; some of them take as much as 45 to 50 calories per lb. body weight in the first twenty-four hours, while others will not; but none of these infants will gain weight after ten days on anything less than 60 calories per lb. body weight a day, and often we have to increase to 100 or more.

Vitamin Therapy.—Vitamin concentrates are administered to all our premature infants from a very early date. Vitamins A and D are added to the feeds in the form of adexolin from the second day of life. 3 minims daily is given at first, and this is gradually increased until 5 minims is being given by the end of the first month. Redoxon (vitamin C) 10 mg. daily is added to the feeds from the fourth week. Infants who have had a difficult delivery or who have haemorrhagic disease of the newborn are given vitamin K as a routine—0.5 to 1 c.cm. kapilon twice daily.

Nursing Technique

Of equal importance to feeding and other measures in the management of the premature infant is the nursing technique. In the Rotunda Hospital the following routine has been most successful. Immediately after birth the cord is ligatured and cut; the baby is cleansed with warm olive oil and wrapped in a warmed gamgee jacket of known weight. Recently, since olive oil can no longer be obtained, we have refrained from washing them altogether, leaving the vernix to fall off gradually. On admission to the nursery the baby is weighed and the rectal temperature taken. A dry dressing is applied to the cord, strict precautions being taken to prevent sepsis; the dressing is kept in place by a flannel abdominal binder. If the infant weighs under 4½ lb. its limbs are wrapped in cotton-wool; if under 4 lb. the head is also wrapped in cotton-wool. Glucose-water and thyroid gr. 1/4 are now given as already outlined; the baby's colour is most carefully observed and the rectal temperature taken again after two hours. If the general condition is not now satisfactory—i.e., if the baby is cyanosed or has birth shock—some form of stimulant is administered, such as nikethamide (coramine), rectal coffee-saline, or brandy. If the condition is satisfactory two-hourly feeding is begun. The baby is subsequently cleansed with olive oil once a day: the diapers are changed five times daily, when the baby is stimulated to induce crying in order to prevent atelectasis: at these times the genitals are cleansed with sterile water and the buttocks rubbed with a cream containing castor oil, zinc oxide, and tinct. benzoini co. The baby is turned on its side every four hours to prevent congestion of the lungs. A bi-daily temperature chart is kept and the baby weighed three times a week.

Infection

Infection is one of the commonest causes of death in the neonatal period. Newborn infants as a rule, and premature ones in particular, have but little power of resistance, and succumb very readily when infected. In an analysis of the causes of death of 101 premature infants in Edinburgh Maternity Hospital it was found that 43 of the deaths were due to infection (McNeil, 1940). Such a finding, however, is not confined to Edinburgh. It has been our experience on more than one occasion, and that of all other maternity hospitals of our acquaintance. The sources of these infections are as a rule:

(*a*) *Fingers of Attendants*.—Organisms are conveyed to the fingers from septic spots on the face or other parts of the body or from masks which have become infected; if the hands are not properly washed, contact with the premature infants implants the organisms on their delicate skin and gives rise to infection.

(*b*) *Improperly Sterilized Feeds and Teats*.—During the early days of life the contents of infants' intestines are sterile, and if their feeds are not thoroughly sterilized they tend to contract a sudden heavy infection with coliform organisms. These are absorbed not uncommonly into the circulation and are later excreted by the kidneys, giving rise to pyelitis and secondary enteritis in both male and female infants.

(*c*) *Droplet Infection*.—This is caused by attendants or visitors, with or without obvious respiratory infection, breathing over the infants; the commonest organisms thus spread are pneumococci, streptococci, and staphylococci.

Infection has been found our greatest difficulty in the Rotunda Hospital nurseries. Again and again it has appeared in spite of the most stringent regulations. During the present year we have had a persistent outbreak of enteritis. As well as enforcing the most stringent regulations regarding the sterilizing of feeds, bottles, etc., and washing of the nurses' hands, we do not now allow admissions from outside the hospital or infected cases from the puerperal wards even to the isolation wards in the nursery. No visitors or students are permitted entry to any of the infant wards. The nurses' nasopharynges are periodically examined and swabbed, and sterile masks are supplied in sufficient quantities to avoid their being worn when permeated by saliva, and the nurses are instructed never to touch them with their fingers once they are adjusted.

Discussion

There is no doubt that the measures necessary to reduce the death rate of premature infants are elaborate and complicated, but the results that may be obtained are so remarkable as to make them well worth while. In the past far too much publicity has been devoted to the maternal complications of obstetrics and far too little to those of the child. If the neonatal death rate is to be reduced, as can so easily be done, a new attitude to the whole subject is essential. A proper paediatric unit must be developed in every maternity hospital. There should be a maternity hospital in every region. For babies born outside the maternity hospitals, units of a similar nature should be set up in all children's hospitals. It can be said that attempting to manage premature babies in the general wards of children's hospitals is almost waste of time, as they will tend to become infected and die.

We have dealt here with the management of the premature baby exclusively, and so far have said nothing in regard to the prevention of the condition. This is largely a social matter that can no longer be ignored. The maternity centre in New York has been able, by pre-natal care, to reduce the percentage of premature births by one-third. In a certain home for unmarried women in Oslo the proportion has been reduced to 2%, compared with 32% still prevailing among women of the same class attending the ordinary obstetrical clinic. Nutrition, sufficient rest, and relief from strain are the most important predisposing factors. In this connexion it is well to mention that cerebral haemorrhage is a common cause of death among premature babies, and recent work suggests that one of the reasons for this is lack of vitamin K in the mother's diet. Women suffering from even mild types of the toxaemias of pregnancy are usually placed upon deficiency diets. In the past obstetricians have often failed to recognize the importance of adding vitamin concentrates to these diets. In all such cases it is wise to give special injections of vitamin K.

Finally, we may sum up the position in regard to prematurity by saying that when a combined effort is made by the obstetrician and the paediatrician a considerable reduction will occur in its incidence and its death rate, and as a result we may expect a general improvement in the whole neonatal mortality.

TREATMENT OF WOUNDS AND INFLAMMATION BY X RAYS AND RADIUM RAYS

BY

N. S. FINZI, M.B., D.M.R.E.
Director, X-ray Department, St. Bartholomew's Hospital

AND

F. FREUND, M.D.Vienna, M.R.C.S., L.R.C.P., D.M.R.E.
Radiologist, E.M.S.

The use of x rays and other radiations in the treatment of wounds and inflammations has been much neglected. Dr. Leopold Freund of Vienna, who was the first to employ x rays for any form of therapy, used them for inflammations more than 40 years ago. One of us treated such cases as long as 36 years ago, and the other has done experimental research work on the basic principles underlying this treatment. The causes of this neglect are various. First, the indications for the treatment were so universal that it came to be looked at askance by the profession, who feared that it was a semi-quack treatment. Secondly, the discovery of the value of x rays and radium γ rays in malignant disease overshadowed their other uses. Thirdly, incorrect dosage was used in the earlier days. It was not until 1928 that it came to be universally realized that the doses previously given were too large and either produced inferior results or caused the late development of telangiectases and atrophy of the skin. Fourthly, it has been found that the action of ultra-violet and sunlight increases the liability to these late changes if larger doses have to be given, as in keloid. Finally, in the earlier days of the use of x rays the penetration, in treating deep-seated conditions, was much too low, so that the surface received an overdose and the deep part an underdose. Also, in those days accurate measurement of the dose, except that administered to the surface, was impossible.

With the very small doses now employed by some radiologists it is possible to carry on treatment, if necessary, for very long periods without the slightest risk of after-effects: this necessity, of course, arises only in the most chronic inflammations. Success has been obtained by ray therapy in such diverse conditions as carbuncle, erysipelas, suppurative parotitis, tuberculous glands, tuberculous peritonitis, actinomycosis, chilblains, whitlow, gas gangrene, osteomyelitis, and many others.

Basis of Treatment

In wounds there are two purposes to which irradiation can be put. One is the acceleration of the healing of clean wounds and the prevention of keloid; the other is to check the local inflammatory reaction, if there is no foreign body or sequestrum present. It does not matter whether the infection is acute, subacute, or chronic, except that one tends to use even smaller doses in acute cases. Experimental research work was done on the mode of action of small doses of x rays at the Holzknecht Institute in Vienna by one of us and by Shuichi Fukase. This gave the following results:

(1) Under treatment with small doses of x rays polymorphonuclear leucocytes in exudates break down more quickly than they usually do. Some think that this increased breakdown of polymorphs may be combined with the liberation of immune bodies and that the acceleration of healing is achieved by this means. (2) Wounds of the skin and of the cornea of animals heal sooner in the part treated locally by x rays. On the shaved skin of rabbits incisions were made about 12 cm. long down to the superficial fascia. One half of the incision was covered with lead and the other half was treated by x rays immediately after the wound was inflicted. The wounds were left open and the animals kept in their usual surroundings. In that part treated by x rays hardly any exudate or other sign of cellular reaction occurred either as to the naked-eye or the microscopical appearance. The treated part of the wound was healed in 8 days as if it had been sewn up. The untreated part became infected and healed slowly by granulation. (Figs. 1 and 2.) Wounds of the cornea healed without surrounding inflammation on the side treated by x rays, but with marked infiltration on the side not treated. (3) Experimentally produced fractures of both fibulae of rabbits heal more quickly on the side treated with x rays. The callus on the irradiated side is less in quantity, is formed earlier, and is more heavily calcified. (4) After the inunction of tuberculin into the skin no reaction takes place in the part of the skin treated by x rays soon after the inunction. This shows the local effect of x-ray

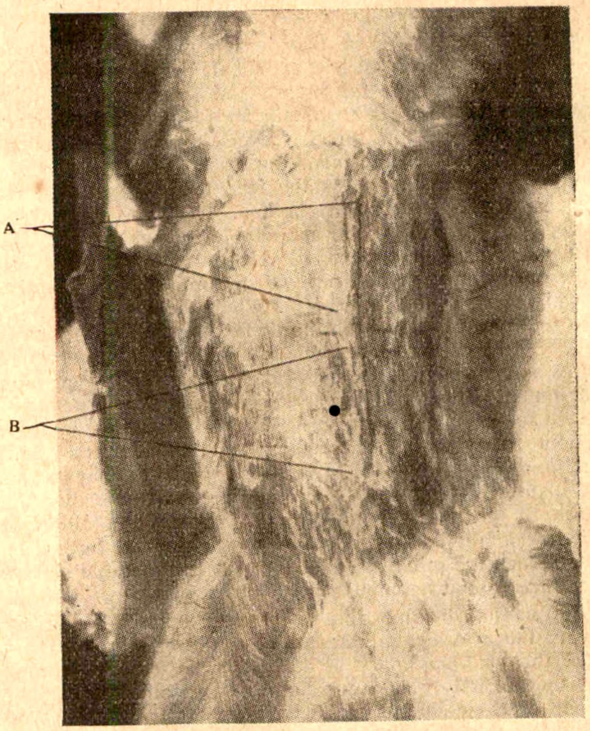

FIG. 1.—Cut in back of a rabbit 5 days after Section A had been irradiated. This section is firmly united, while Section B is still ununited.

treatment on the immunity reaction. The most striking result in all these experiments is the prevention of gross inflammatory reactions as seen both macroscopically and microscopically. Exudates are prevented and any inflammatory cells are rapidly changed to fibrocytes and fibrous tissues. This change, which always normally occurs in inflammatory reactions when sound natural healing takes place, can be induced and accelerated artificially by *small* doses of x rays. If *bigger* doses are used, reversed effects and even necrosis occur, probably on account of the fact that inflamed tissues are much more radiosensitive than normal tissues. It seems to be of specific value in checking *local* inflammatory reactions which are of no further use in defence. Sometimes a mild infective agent will elicit abundant cellular reaction in the body and thus endanger life. In these cases irradiation is most useful by cutting short this inflammatory allergic reaction.

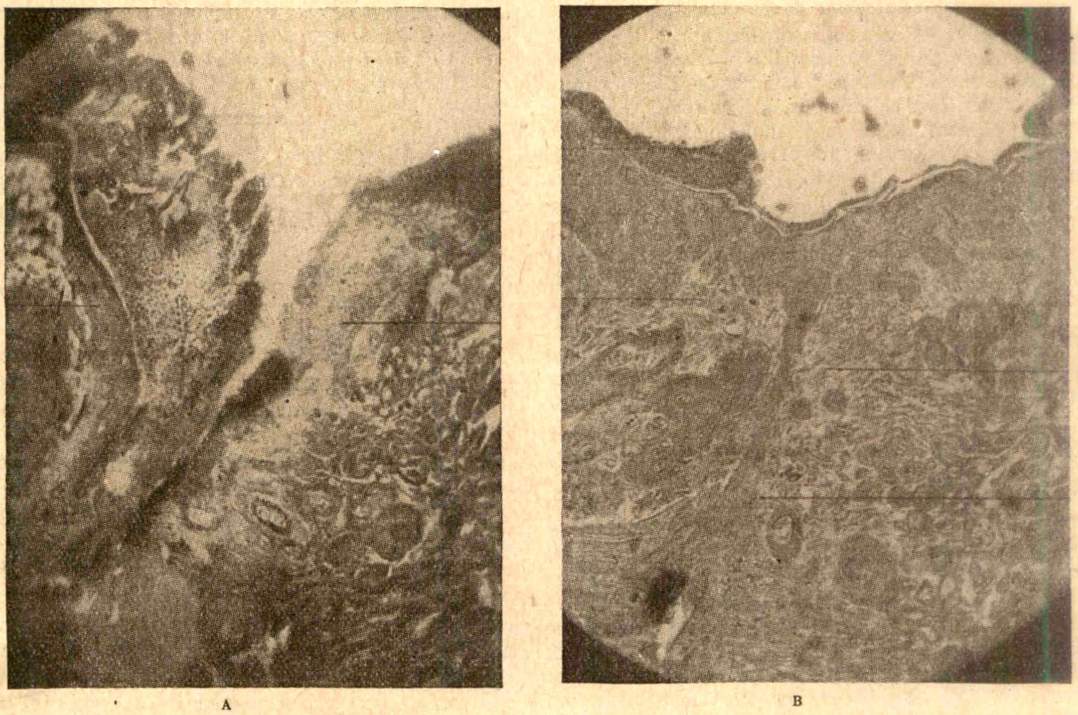

FIG. 2.—(A) Untreated wound after 5 days shows no union. (B) Treated wound after 5 days shows firm union.

Indications for Use of Irradiation

Delay in Natural Healing.—Wounds of the surface which do not heal are quickly cured by treatment with the small doses of x rays mentioned. After a day or two the process of healing can be recognized by loss of pain; the exudation gradually subsides, frequently after a preliminary increase; the closure of the wound and the growth of the epithelium are both accelerated; callous chronic ulcers soon become covered with healthy granulations and heal. In fractures in which bony union has not occurred x-ray treatment induces quick calcification and bony union. Similar healing takes place in those haematomata which do not heal quickly—e.g., haematoma of the pinna of the ear.

Failure of Surgical or Medical Treatment.—In any inflammation where surgical or medical treatment fails, irradiation with small doses of x rays is indicated. As an example of failure of surgical treatment osteomyelitis following whitlow may be mentioned: loss of part of a finger, even in advanced cases, is generally unnecessary. With x-ray treatment we get regeneration of bone which is almost decalcified and destroyed by osteomyelitis (Figs. 3 and 4). Much disability in workmen, munition workers, men in the Forces, artists, housewives, and

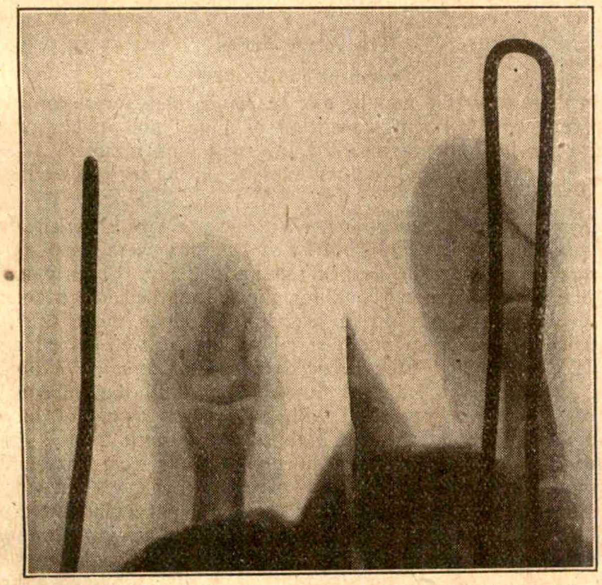

FIG. 3.—Whitlow before x-ray treatment. Amputation had been advised.

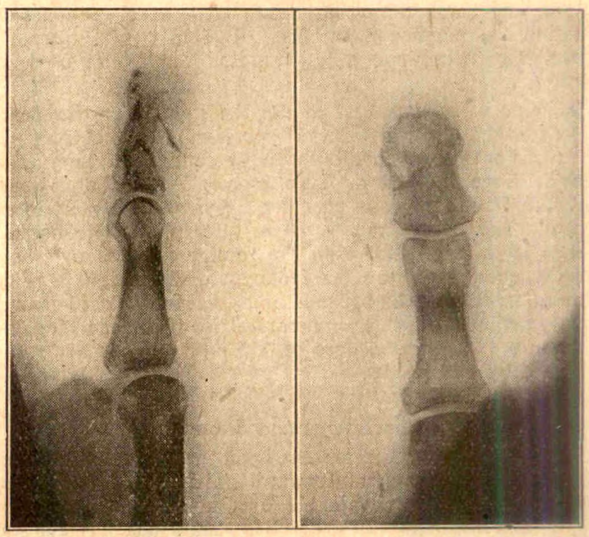

FIG. 4.—Whitlow 3 months after x-ray treatment was begun. Seven weekly doses of 100 r (surface) were given, and, later, two more doses of 100 r.

others is prevented. All other forms of osteomyelitis are indications for *x*-ray therapy combined with the necessary surgical treatment. Amputations with their consequent disability may be avoided. Great claims have been made in the United States for the use of this treatment in gas gangrene. Parenthetically, as an example of failure of medical treatment post-herpetic neuralgia may be mentioned. The treatment of the posterior root ganglia by *x* rays is followed by quick cure. Trigeminal neuralgia also responds to irradiation of the Gasserian ganglion.

Acute Inflammations.—Carbuncles of the upper lip, some forms of erysipelas, cellulitis, lymphangitis, gas gangrene, and osteomyelitis of the skull should be treated at once with *x* rays. No harm whatsoever can be done by using small doses on a limited field, whereas delay may sometimes prove fatal. In very few cases of infection, however, the treatment fails to improve the condition.

Subacute and Chronic Inflammations.—The number of these conditions is very large; we will instance only a few. Good examples are actinomycosis, local tuberculous infections as of lymph nodes or mucous membrane, chronic osteitis, septic fingers, and other local septic conditions.

Prevention of Disfigurement.—Scars are much better, thinner, and less obvious in wounds that are treated by *x* rays, and keloid will be prevented if irradiation takes place soon after trauma. This treatment is now often employed by plastic surgeons.

Social Indications and Wartime Purposes.—Delay in healing of all kinds of inflammation may be of importance from its economical or its wartime aspect. Healing can be much accelerated by irradiation and the period of incapacity therefore considerably shortened.

Dosage

The wave-length does not seem to be of great importance if the lesion receives the same biological dose. This is not the same thing as the physical dose, because a larger number of roentgens (*r*) have to be given if the wave-length is shorter, in order to produce the same biological result. Nevertheless, Fukase has shown experimentally that the shorter wave-lengths give better results. Grenz rays* are not sufficiently penetrative to give the requisite lesion dose.

The accurate modern methods of measurement enable us to calculate the dose received by the lesion whether it is superficial or deep. Though a very large dose is definitely harmful and the optimum dose is very small, there is considerable latitude. Thus, double the optimum dose will still give a good result, though not the best. The dose to be received by the lesion lies between 30 *r* and 80 *r*. The former dose may be applied twice a week and doses from 50 *r* upwards once a week. This dose presumes the use of *x* rays of about 140 kV constant current with a filter of Al 5 mm. With higher voltage and filtrations the number of *r* must be larger to give the same biological dose; with lower voltages and filtration the number is smaller. Radium γ rays filtered by Pt 0.5 mm. necessitate a lesion dose double that used with medium *x* rays.

In acute cases it is best to use the smaller dose, repeating in 3 days, and again in 4 days if necessary. With chronic cases treatment may occasionally have to continue a long time—two or three months or even more. A case of extensive abdominal actinomycosis even took one of us a year to cure finally. The dosage rate is 10 to 80 *r*/min. The necessary dosage is so small that even the routine fluoroscopy is occasionally enough to stop the inflammatory reaction. Children with enlarged bronchial glands and constantly raised temperature sometimes lose this temperature rise if screened for about 5 minutes. A repeated dose of 150 *r* or more is likely to be followed by bad results.

Conclusions and Summary

Owing to the war the present is an important time to bring this method of treatment forward. The use of radiations in these cases is a very valuable one, and will without doubt much increase in the future, when experience has confirmed the good results, which cannot be achieved by any other means.

The treatment of acute, subacute, and chronic inflammations by small doses of *x* rays is described, as well as the experimental and research work on which this treatment is based. The accelerated healing of wounds and fractures by irradiation is also described. The effect of *x* rays is due to the influence on local cellular reaction and local immunity. The reasons for the neglect of this treatment are gone into. The necessity for small doses is stressed, both for the better results and for the absence of late bad effects.

THE USE OF SULPHAGUANIDINE IN BACILLARY DYSENTERY

BY

ANGUS E. BREWER, M.R.C.S., L.R.C.P.
Capt., R.A.M.C.

The cases surveyed in this paper were selected for treatment from 600 patients suffering from bacillary dysentery admitted to a general hospital in the Middle East over a period of 8 months. Of these, 77 were treated with sulphaguanidine. Its use was authorized only in severe or refractory cases. Hence the acute cases described represent those which from general experience of dysentery could not be expected to do well on standard treatment, and the chronic cases those which had already failed when so treated. There was occasionally a temporary shortage of supply, but every effort was made to give what was considered to be an adequate course of the drug. Sulphaguanidine consists of sulphanilamide in which one of the hydrogen atoms of the amino group is replaced by a guanidine ring, and is thus homologous with sulphathiazole and sulphapyridine. Experimental investigation has shown that sulphaguanidine, although water-soluble, is poorly absorbed by the intestinal mucous membrane. This would allow large concentrations to be maintained in the gut, with only a low tissue fluid and blood concentration resulting, and a correspondingly slight danger of toxic poisoning from large or prolonged dosage.

Of the 77 cases 26 were classed as acute and 51 as chronic. This differentiation was based mainly on the day of disease, and all cases giving a history of less than 2 weeks from the onset were considered acute. Duration of symptoms in the cases termed chronic varied from over 2 weeks to many months.

The Acute Series

Treatment and Routine

In these cases the malaise and toxaemia were severe and the motions very frequent, consisting of blood and mucus only. The majority had not received any treatment, although a few had had castor oil and sodium sulphate during their evacuation to this hospital.

Dosage of Sulphaguanidine.—With no previous experience as a guide the following arbitrary indications were used as a means of gauging the dosage required: 3.5 g. 4-hourly until (*a*) the patient's general condition showed marked improvement as evidenced by a drop in temperature, clean moist tongue, absence of toxaemia, and general feeling of well-being; and (*b*) the stools had been reduced to five or less in 24 hours and were faecal. 3.5 g. 4 times a day until the infrequent stools became a semi-solid with only slight traces of blood and mucus present. 3.5 g. 3 times a day until 2 or 3 days after the stools had become normal. Stools were considered normal when not more than two solid or nearly solid stools without blood were passed in a day. No particular attention was paid to a small excess of mucus, which was almost invariably present. In the early cases treated this latter part of the plan was not strictly adhered to and sulphaguanidine was stopped on the day the stools were free from blood.

On admission the patient was generally somewhat collapsed. He was put to bed, rested and warmed, and his clinical condition observed for the first few hours. During this time the frequency and character of stools were noted and specimens sent to the laboratory for plating and microscopy. Treatment with sulphaguanidine was started with an initial dose of 7 g. in the form of a powder stirred up in 2 oz. of water. In very severe cases this was followed by 3.5 g. in 2 hours, and again after 2 more hours. Otherwise the 3.5-g. doses were repeated at 4-hourly intervals. The diet was limited to fluids for the first 24 hours of treatment, after which mashed potatoes, fish, chicken, junket, and bread-and-butter were gradually added until on the third or fourth day the patient was receiving a full diet. No difficulty was encountered in getting patients to eat, as the desire for food returned almost invariably in the first 48 hours. Every effort was made to encourage a large fluid intake by mouth in the early stages to replace fluid loss. In no case was intravenous fluid found to be necessary.

The following adjuvant treatment was carried out: (1) In the case of Shiga infections, 30,000 units of antiserum; (2) mist. bismuth. c̄ creta, 1 oz. every hour, in the initial stages of treatment to aid in reducing the frequency of the bowel motions; (3) tinct. opii in 10-minim doses, or occasionally 1/4 gr. of morphine, to relieve abdominal pain.

Sigmoidoscopy was carried out during the week after treatment, and subsequently if a normal mucosa was not seen the first time. Sigmoidoscopy as a routine measure before treatment did not seem justifiable. The rectum was, however, examined in a few cases, and showed a typical picture of sloughs separating to leave intensely congested and bleeding surfaces with varying oedema and induration. In acute cases the general condition and a stool examination would seem to be an adequate means of assessing the intensity of the infective process. The urine was tested daily and a blood count done at completion of treatment.

TABLE I.—*Acute Cases*

No. of Case	Clinical Nature	Day of Disease	Bacteriology	No. Days Treatment	Total Dosage (g.)	Day of Marked General Improv.	Day Stools Faecal	Day No Abdom. Tender	Day No Abdom. Pain	Day Stools Normal	Remarks and Sigmoidoscopic Findings

Out of a total of 26 acute cases treated 16 were Shiga, 6 Flexner, and 4 undetermined culturally but having a typical bacillary exudate in the faeces. Table I gives the cases in descending order of dosage and grouped according to cultural findings, except that those not completely cured and not showing a healed mucosa on sigmoidoscopy are grouped at the bottom. The cases are classed as severe or very severe according to their clinical condition on admission to hospital.

Cases Completely Cured.—Of the 26 cases 19 were cured, of which 11 were severe and 8 very severe. Table II shows the days on which recovery from symptoms occurred.

TABLE II.—*Showing Days of Recovery from Symptoms*

	Severe Cases (11)	Very Severe Cases (8) (All Shiga)
Average total dose	110 g. over 9 days	180 g. over 12 days
Marked general improvement ..	2 to 4 days	3 to 10 days
Stools became faecal	2 to 5 days	5 to 10 days
No abdominal tenderness ..	3 to 5 days	4 to 10 days
No abdominal colic	2 to 4 days	3 to 9 days
Normal stools	5 to 8 days	8 to 14 days

It is interesting to note the quick response to treatment of Cases 11 and 14 (Table I), both of which were severe Flexner infections treated on the first and the second day of onset respectively. Treatment lasted a week, with a total dosage of 91 g., and in spite of the severity of the infection stools were formed, and without blood, on the fifth day, the patient being discharged from hospital in full health 14 days from the onset of disease.

Cases Not Completely Cured.—These cases numbered 7—5 severe and 2 very severe. In the severe cases the average total dose was only 90 g. over 6 days and the response of symptoms to treatment occurred as in the cured cases. Sulphaguanidine was stopped on the day stools became normal. These cases continued to improve for a few days and then suffered a relapse, although not of a very acute nature. Stools became loose, 4 to 10 daily, with blood and mucus. There was some return of colic and abdominal tenderness. In all cases sigmoidoscopy showed moderate hyperaemia and granulation of the mucosa, accompanied by a variable degree of oedema, induration, and bleeding from actual induration. Subsequent treatment with colonic wash-outs produced complete healing in from 2 to 4 weeks. As both the very severe cases were Shiga infections they are here described separately:

Case 16.—Sulphaguanidine was stopped owing to a shortage of supply after 136 g. had been given over 7 days. The response to treatment was quite satisfactory, with the disappearance of symptoms and the return of faeces to the stools. The latter, however, still contained mucus with very slight traces of blood the day treatment had to be suspended. No further improvement was seen and the case became chronic, with up to 6 loose stools daily containing blood and mucus. Shiga's bacillus was again isolated from the stools, and sigmoidoscopy showed much induration and oedema of the bowel-wall, with a coarsely granular hyperaemic surface, nodular in places and covered by muco-pus which was expressed from pockets by passage of the instrument. Colonic wash-outs effected a temporary improvement only, and after 5 weeks a further course of sulphaguanidine—175 g. over 10 days—was given. Subsequent sigmoidoscopy revealed a healed mucosa.

Case 23 showed an initial response which was not sustained: although blood disappeared on the sixth day the stools remained as frequent as 20 or more a day. Malaise and toxaemia, with abdominal colic and tenderness, were marked. Sulphaguanidine was continued until 350 g. had been given over 20 days, but without improvement in the patient's condition. Repeated sigmoidoscopy showed an oedematous and injected mucosa without ulceration. Shiga's bacillus was again isolated after 100 g. of sulphaguanidine had been given.

Case Reports (Acute Cases)

Case 10.—This is an example of the very severe cases that were cured. Dec. 1: Gradual onset of symptoms; no treatment was received, and the condition had steadily increased in severity until admission to hospital on Dec. 11. Admitted very weak, pale, exhausted, and in a collapsed condition. Temperature 97.4°; pulse 120; abdominal pain very severe. Stools showed almost continual passage of blood and mucus. Morphine 1/4 gr. was given; hot blankets, water-bottles, etc. Some hours later temperature was 102° and pulse 110; treatment with sulphaguanidine was begun. Treatment of the case continued as follows:

Day of Dis.	P.M. Temp. & Pulse	General Condition	Stools		Ab-dom. Tender	Colic	Sulpha-guanidine
			No.	Nature			
10	102°/110	As above	+++	B. & M. only +++	+++	+++	7 g stat. 3·5 g. after 2 hrs. + 3·5 g. ditto
11	101°/90	Slight improv.	20	B. & M only ++	+++	++	3·5 g ×6
12	100°/90	LS Q.	8	B. & M. only ++	++	++	3·5 g. ×6
13	99·2°/90	"	+6	B. & M. only ++	++	++	3·5 g. ×6
14	99·4°/90	"	+6	B. & M. only ++	+	++	3·5 g. ×6
15	99·2°/85	Still much malaise and toxaemia	+4	Slightly faecal, mostly B. & M. only +. 3 faecal B. ++ / M. ++	Slight	+	3·5 g. ×6
16	99°/85	" "	4	1 B. & M. only	Slight	+	3·5 g. ×6
17	N.	Marked improv.	3	Semi-solid. B. & M. ++	0	0	3·5 g. ×4
18	N.	Improv. contd.	2	Semi-solid. M. ++	0	0	3·5 g. ×4
19	N.	"	1	" "	0	0	3·5 g. ×3
20	N.	"	1	Solid. Slight M.	0	0	3·5 g. ×3

Adjuvant treatment was as follows: 10th day—morphine gr. 1/4×2; anti-Shiga serum, 30,000 units; mist. bism. cret, 1 oz. q.h. 11th to 14th days—mist bism., tinct. opii ♏ 10×4. Adjuvants were then stopped.

The stools remained normal except for a slight excess of mucus, and sigmoidoscopy showed a healed mucosa with an occasional submucous haemorrhage. The urine was normal throughout. A final blood count after treatment showed: Hb 96%, R.B.C. 4,910,000, W.B.C. 5,300, with normal differential count.

Case 11.—This case illustrates the quick response to early treatment in comparison with Case 10. In the early morning of Sept. 28 the patient was taken with sudden diarrhoea and abdominal colic, blood appearing in the stools after a few hours. Marked vomiting and tenesmus were present. Sixteen hours after onset admitted to hospital collapsed, with severe abdominal colic. Tongue furred and dry; abdomen showing marked tenderness; stools slightly faecal, with much blood and mucus. The severity of the symptoms suggested a Shiga infection, and 30,000 units of antiserum were given, although the report received 2 days later indicated a typical Flexner bacillus.

Day of Dis.	P.M. Temp. & Pulse	General Condition	Stools		Ab-dom. Tender	Colic	Sulpha-guanidine
			No.	Nature			
1	101°/100	As above	+15	First faecal, becoming B. & M. only	+++	+++	7 g stat.
2	99·4°/80	Marked improv. at end of day	+5	Occ. faecal. B. & M only ++	++	++	3·5 g. ×6
3	N.	—	3	Fluid. Faecal. B. + M. +	0	0	3·5 g. ×6
4	N.	—	3	Semi-solid. M. +	0	0	3·5 g. ×4
5	N.	—	1	" "	0	0	3·5 g. ×4

Adjuvant treatment given was: 1st day—morphine gr. 1/4, mist. bism. cret. 1 oz.; antiserum 30,000 units q.h.; 2nd day—tinct. opii ♏ 10×2.

The stools remained normal and sigmoidoscopy showed a healed mucosa. Urine normal. Blood count normal.

The Chronic Series

These patients had been suffering from chronic dysentery for from a few weeks to many months, and all had received various periods of routine treatments.

Dosage.—Indications as to dosage were again purely arbitrary and, as in the acute series, the nature of the stools passed was taken as a guide, sulphaguanidine being continued until 2 days after the stools had become normal. Of 20 cases so treated, 9 were not cured. In these, symptoms returned and sigmoidoscopy showed that although the stools were microscopically normal the mucosa had not healed. It was evident that this plan of dosage, although satisfactory in acute cases, when used in the chronic cases resulted in too small a total dosage and too short a period of treatment. Accordingly a new scheme was adopted whereby all the cases were treated for a minimum of 8 days, 3.5 g. of sulphaguanidine being given at 4-hourly intervals, omitting the 2 a.m. dose. The total daily dose was therefore 17.5 g. The number of days under treatment was increased in cases of more than average severity, where such was indicated by the degree of toxaemia of the patient, sigmoidoscopic appearances, and length of illness.

Treatment and Routine

Preliminary to Sulphaguanidine.—Most cases gave a history of previous treatment with sodium sulphate and fluid diet. Cases 6, 23, 25, 26, and 51 had received from 30 to 80 g. of sulphaguanidine in the acute phase (i.e., during their evacuation), but treatment had not been continued until the stools were normal. 19 cases received a period of treatment (after admission here) with colonic wash-outs while on a low-residue diet. Sigmoidoscopy sometimes showed temporary improvement, but complete healing did not take place.

With Sulphaguanidine.—During the first few days the patient's general condition was observed, nature of stools noted, and sigmoidoscopy carried out, material being removed for microscopical examination and plating. The sigmoidoscopic appearances are illustrated in case notes given below. Diet was the same as in the acute cases. The urine was tested daily, and a blood count done at the end of treatment.

Description of Chronic Cases

Of the 51 chronic cases treated, 20 were Shiga infections, 14 Flexner, and 17 unidentified. They are described in two groups: Group A, in which the original plan of dosage was used, and Group B, in which the modified plan was used. Table IV shows both groups in descending order of dosage.

Group A.—This consisted of the first 20 cases treated, and the average total dose was 90 g. over 6 days. All responded to treatment, and in from 3 to 6 days the stools had become normal, abdominal tenderness and colic had disappeared, and the patients' general condition had greatly improved. Yet only 11 (55%) cases showed complete healing on sigmoidoscopy. In the other 9 granular hyperaemic areas with some induration and oedema remained. There was some return of symptoms, and complete healing took several weeks, during which period the patients remained on a low-residue diet and received daily colonic wash-outs.

Group B.—This series consisted of the subsequent 31 cases, and the average total dose was 160 g. over 10 days. Symptoms responded to treatment as in Group A, but the final results were much better in that 24 (77%) cases showed complete healing on sigmoidoscopy and 5 complete healing except for granular hyperaemic patches limited to the lower part of the rectum. These had disappeared after one week's treatment with rectal wash-outs, during which time the patient was given liquid paraffin to soften the stools. Two cases (Nos. 33 and 45) which appeared to respond quite well suffered a subacute relapse when treatment was suspended. Sigmoidoscopy showed a return of ulceration on an oedematous indurated hyperaemic mucosa. Treatment with colonic wash-outs was tried again, but the lesions did not heal completely. A further course of sulphaguanidine—189 g. and 175 g. respectively—resulted in cure.

Table III (including both groups) shows the average day, the earliest day, and the latest day on which recovery occurred.

TABLE III

	Average Day	Earliest Day	Latest Day
Marked general improvement	3rd	2nd	7th
No abdominal tenderness ..	4th	3rd	7th
No abdominal colic .. .	4th	2nd	9th
Normal stools	4th	3rd	10th

Case Reports (Chronic Cases)

Case 13.—This case was from Group A and was treated according to the original scheme of dosage without complete cure. In the acute phase of an attack of dysentery in Sept., 1941, after 4 months in the Middle East, the routine saline treatment was given for 10 days with improvement, but the stools never became normal. When admitted here a month later (Oct. 3) he was pale, thin, and toxic, with temperature 99° to 100° and pulse 80 to 110. There was marked tenderness over sigmoid, ascending colon, and caecum. The stools, about four daily, contained much bloody mucus. Sigmoidoscopy showed numerous irregular ulcers with overhanging edges covered by yellowish muco-pus, which on removal left a bleeding granular floor. Some ulcers had become confluent, and the intervening mucosa was granular, slightly indurated, and oedematous. The exudate was bacillary in type, but culture from swabs proved negative. From Oct. 17 to 27 treatment was carried out with colonic irrigation. The patient's condition would improve for a few days and then relapse. Stools continued to contain blood and mucus. Sigmoidoscopy now showed much increase in the oedema and induration of the bowel wall, and instrumentation was impossible beyond 10 cm. The ulcers had not healed. Culture from a swab again proved negative. Therapy with sulphaguanidine was started on Nov. 3, and was continued as follows, 70 g. in all being given:

Day of Dis.	P.M. Temp. & Pulse	General Condition	Stools		Abdom. Tender	Colic	Sulphaguanidine
			No.	Nature			
52	100°/90	As above	4	S-S. B. + M. ++	+	+	7 g. stat. +3·5 g. ×2
53	99°/90		1	S-S. B + M. ++	+	0	3·5 g. ×5
54	98 4°/90	Slight improv.	0	—	+	0	3·5 g. ×4
55	N./85	Marked improv.	0	—	0	0	3 5 g. ×4
56	N./N.	Improv. contd.	1	S. M.	0	0	3·5 g. ×3

After a few days stools were again loose, with occasional blood-streaked mucus. Sigmoidoscopy showed a great improvement, but indurated, oedematous, bleeding granular areas remained. From Nov. 13 to 28 treatment was continued by colonic irrigation, and sigmoidoscopy one week later showed a healed mucosa.

Case 28.—This was a severe case from Group B, and was treated according to the revised scheme, with complete cure. At the onset of an acute attack of Shiga dysentery in Nov., 1941, after 3 months in the Middle East, routine saline treatment was given with initial improvement but subsequent acute relapse; on Dec. 1, when admitted here, saline treatment was repeated, and was followed by colonic irrigation. On Dec. 28, 2 months after the onset, stools were about 5 daily, and contained much blood-stained mucus; chronic toxaemia was gradually worsening the patient's condition. Sigmoidoscopy showed numerous irregular-shaped ulcers covered with blood-stained muco-pus. The rest of the mucosa was granular and haemorrhagic, and in some places nodular. Pus was expressed from between the nodules by the passage of the instrument. Oedema and induration of the bowel wall became so great that instrumentation was impossible beyond 12 cm. Treatment with sulphaguanidine was started on Dec. 29—the 55th day of disease—and continued as follows (total dosage, 175 g.):

Day of Dis.	P.M. Temp. & Pulse	General Condition	Stools		Abdom Tender	Colic	Sulphaguanidine
			No.	Nature			
55	99 8°/90	As above	5	S-S. B. + M. +++	++	+	7 g. + 3·5 g ×3
56	99 8°/90		2	S-S. B. + M ++	+	+	3·5 g. ×5
57	99 2°/90		1	S-S. B. M. ++	+	Occ.	3 5 g. ×5
58	N./90	Marked improv.	2	S-S. M. +	+	Occ.	3·5 g. ×5
59	N./85	Improv. contd.	1	S. M. +	0	0	3·5 g. ×5
60	N./N.	,,	2	S-S.	0	0	3·5 g. ×5
61	N./N.	,,	1	S.	0	0	3·5 g. ×5
62	N./N.	,,	1	S.	0	0	3·5 g. ×5
63	N./N.	,,	1	S.	0	0	3·5 g. ×5
64	N./N.	,,	1	S.	0	0	3·5 g. ×5

Stools remained normal, and sigmoidoscopy one week after treatment showed a completely healed mucosa.

Case 47.—A moderate case from Group B showing complete healing but some residual proctitis. At the onset of an acute attack of dysentery on Dec. 4 routine saline treatment was given. Admitted here on Dec. 14 much improved, but still with loose faecal stools containing blood and mucus. Sigmoidoscopy showed a granular hyperaemic mucosa, covered by blood-stained muco-pus, with moderate oedema and induration of the bowel wall. Culture was negative. From Dec. 20 to 30 colonic irrigation and low-residue diet. On Jan. 6 stools were still loose, with blood and mucus. Sigmoidoscopy showed no healing. Treatment with sulphaguanidine was started on Jan. 7—the 33rd day of disease—and was continued as shown, the total amount given being 140 g.:

Day of Dis.	P.M. Temp. & Pulse	General Condition	Stools		Abdom. Tender	Colic	Sulphaguanidine
			No.	Nature			
33	99·2°/85	Malaise and toxaemia +	3	S-S. B. + M. +	+	+	7 g. + 3·5 g. ×3
34	98·6°/N.	,, ,,	0	—	+	+	3 5 g. ×5
35	N./N.	Marked improv.	1	S. M. +	0	0	3·5 g. ×5
36	N./N.	,, ,,	0	—	0	0	3·5 g. ×5
37	N./N.	Improv. contd.	0	—	0	0	3·5 g. ×5
38	N./N.	Slight toxic effects here—malaise, anorexia, erythema [N B. Bowels confined]	1	S. M. +	0	0	3·5 g ×5
39	N./N.	—	1	S.	0	0	3 5 g. ×5
40	N./N.	Rash gone. [N.B. Bowels open]	2	S-S. M.	0	0	3·5 g. ×5
41	N./N.		2	S-S.	0	0	3·5 g. ×5

Sigmoidoscopy showed a healed mucosa except for hyperaemic granular patches with slight oedema and induration in the rectum. Stools were loose for 4 to 5 days, with flecks of blood-stained mucus. Treatment was continued with rectal wash-outs and liquid paraffin for 10 days. On Jan. 27 sigmoidoscopy showed the rectal lesions to have healed, and stools were quite normal, with patient fit and well.

Toxicity of Sulphaguanidine in Chronic Series

Toxic symptoms were rare, occurring in only 9 patients out of 51 chronic cases treated. (No toxic symptoms occurred in the acute cases.) They comprised rashes, nausea, headache, tachycardia, and fever (see Table V). It will be seen that in all but 2 cases a dose of at least 100 g. had been given, and it was noted that all patients with toxic symptoms were relatively constipated—i.e., one stool in 2 or 3 days. It is therefore reasonable to assume that the concentration of sulphaguanidine in the bowel was unusually high and that this may have led to increased absorption into the blood stream.

TABLE V.—*Toxic Symptoms*

Case	Day of Treatment	Dosage Given (g.)	Symptoms	
			Duration	Nature
51	12th	224	3 days	Macular red rash on trunk; headache and tachycardia
34	9th	157·5	2 „	Slight fever; tachycardia; headache; nausea

6	4th	4	2 „	Slight fever; headache; nausea

Conclusions

Acute Cases

In all, 26 acute cases of bacillary dysentery were treated with sulphaguanidine. 19 cases were completely cured in from 14 to 21 days; 6 cases relieved, 1 of which became chronic; and 1 case hardly affected. The chronic case was subsequently cured by further treatment with sulphaguanidine.

Sulphaguanidine, like other sulphonamides, would appear to be bacteriostatic, the dysentery bacilli dying only slowly. Hence an efficient concentration of the drug must be maintained for some time after the active infective process has been inhibited. Such a stage is evidently reached when the stools are almost normal, and the failure to continue the sulphaguanidine makes a relapse likely. Cases 1, 2, 3, 4, and 5 were the first treated, and sulphaguanidine was stopped when the faecal stools had a consistency and showed no blood. The fact that these cases relapsed after a few days would appear to stress the importance of continuing treatment for 2 to 3 days after the stools are normal and while the final stages of healing are taking place. Further evidence in support of this is given by Cases 6, 23, 25, 26, and 51 of the chronic series, which received up to 80 g. in the acute phase but subsequently became chronic. Treatment had not been continued until the stools were normal.

The early acute infections showed a very quick response to treatment, and the longer the interval between the onset of the disease and the beginning of treatment, the longer was treatment necessary.

The more frequent and looser the stools the less the concentration of sulphaguanidine in the bowel (*Trop. Dis. Bull.*, 1942, **39**, 34), and in the initial stages of treatment adjuvants such as tinct. opii, bismuth and chalk, and kaolin were used to lessen the frequency and increase the consistency. In the one case which failed to respond the stools remained fluid and frequent in spite of all treatment.

The feeling of well-being as toxaemia is overcome and the early fall in the frequency of the stools greatly reduced the exhaustion and dehydration of the patient. Fluid can be made up adequately by mouth, and the patient's early desire for food as his condition quickly improves allows his strength to be built up while the infective process is overcome.

Chronic Cases

A series of 51 cases of chronic bacillary dysentery were treated with sulphaguanidine. All showed an early and marked response to treatment. In the first 20 cases, as in the acute series, the nature of the stools governed the dosage given, and the average total dose was about 90 g. over 6 days. Only 11 (55%) cases were completely healed, without relapse. In the subsequent 31 cases a minimum dosage of 17.5 g. for 8 days was given, and the advent of normal stools was not taken as an indication for reducing or stopping treatment. The average total dose was 160 g. over 10 days. 24 (77%) cases showed complete healing, and 5 complete healing but for granular patches in the rectum; 2 responded but relapsed after treatment.

Stool examination and the general examination of the patient are inadequate as a means of gauging the state of the lesions in the bowel, and sigmoidoscopy is essential. It would seem that passage of normal stools and disappearance of symptoms in chronic cases indicate only that the active infective process has been inhibited and not that healing of the mucosa has taken place. If sulphaguanidine is not continued the infective process may again become active, delaying healing for some weeks. A full daily dose of 17.5 g. for at least 8 days, and longer in cases showing other than moderate severity, would appear to afford adequate protection against this delay in healing. Nine cases of the chronic series showed mild toxic symptoms from the sulphaguanidine.

Summary

In all, 77 cases of bacillary dysentery were treated—26 acute, 51 chronic. Of the 26 acute cases 16 were Shiga infections, 6 Flexner, and 4 unidentified. Of the 51 chronic cases 20 were Shiga and 14 Flexner infections; in 17 the organism was undetermined.

Patients were put to bed, rested and warmed. The frequency and character of stools were noted, and specimens plated and examined microscopically. Diet was limited to fluid in the first 24 hours. A large fluid intake by mouth was encouraged in the early stages to replace fluid loss. No intravenous fluid was necessary.

Adjuvant treatment was given, cases of Shiga infection receiving 30,000 units of antiserum.

Acute cases received an initial dose of 7 g. of sulphaguanidine, followed by 3.5 g. at 4-hourly intervals. In very severe cases 3.5 g. was given 2 hours after the initial dose, followed in 2 hours by a further 3.5 g. In the main, sulphaguanidine was given until 2 days after the stools had become normal.

Chronic cases received 17.5 g. of sulphaguanidine daily, in 5 doses, for a minimum of 8 days, the length of treatment being increased in the severer cases. A preliminary period of treatment with colonic wash-outs while on a low-residue diet was carried out in 19 cases.

In chronic cases sulphaguanidine must be given until healing of the mucosa has taken place: to gauge this, sigmoidoscopy is essential.

Complete cure was obtained in 19 (73%) acute cases, in 11 (55%) chronic cases receiving 90 g. over 6 days, and in 24 (77%) chronic cases receiving an average dose of 160 g. over 10 days.

Toxic symptoms occurred in only 9 of the 51 chronic cases; there were none in the acute series.

Illustrative cases, showing the scheme of treatment, are recorded.

PROBABLE TETANUS DESPITE INOCULATION WITH TOXOID

BY

R. J. McGILL, M.B.

Temp. Major, Indian Medical Service; O.C. Medical Division of an Indian General Hospital, M.E.F.

Preliminary reports upon battle casualties previously protected with tetanus toxoid seem to vindicate both its use and the administration of two doses at a six-weekly interval. In the B.E.F. in France and Flanders no tetanus occurred in the wounded who had been so inoculated (Perry, 1940), and the third dose after a six-months interval, which is now the standard method advocated by Boyd (1938) and in practice in the British and Indian Armies, should further raise the antitoxin level. The following is a probable case in a subject who had been protected by two doses at a six-weekly interval.

Case History

A sepoy aged 20 received 1 c.cm. of tetanus toxoid subcutaneously on April 25, 1941, and again on June 7 (as recorded in his pay-book). He was admitted to this hospital on Dec. 4 with a history of stiffness in the dorsal thoracic muscles and the muscles of the back of the neck for two days. Slight stiffness of the jaws and dysphagia appeared first on the day of admission. His only injuries were a wound on the left thenar eminence and one on the palmar surface of the left middle finger, each about 3/4 in. long, incised, superficial, and at the time of admission quite healed, with only the edges of the most superficial horny layer very slightly gaping. He had received them on Nov. 18 while serving on the Red Sea Littoral.

Moderate risus sardonicus and trismus were present, the jaws opening 1/2 in. There was marked stiffness of the back and neck. One could just pass the flat of the hand between the shoulders and the bed. The abdominal muscles were rigid, but moved with respiration. Spontaneous paroxysms of opisthotonos were occurring about every half-minute; they lasted about 5 seconds, and were accompanied by clenching of the jaws and spasm of the thoracic and abdominal muscles. The limbs were unaffected. These paroxysms had first appeared on the night of Dec. 3. He was quite rational, but his face bore an appearance of intense anxiety. The only findings of note in the C.N.S. were loss of plantar reflexes (a usual finding in the sepoy in health* and disease) and a complete absence of abdominal reflexes. The pupils were moderately small, and reacted normally to light.

The patient had received 15,000 units of A.T.S. (therapeutic) in his unit on the previous day, and 15 c.cm. intravenously and 5 c.cm. subcutaneously with adrenaline and calcium lactate in a reception station earlier on the day of admission. (There he had also undergone lumbar puncture, the fluid revealing no abnormality of pressure or constituent.) In this hospital he was given 40,000 units (therapeutic) intramuscularly b.d., and was kept stuporous with 4 drachms of paraldehyde by mouth, the paraldehyde being repeated in 2-drachm doses when necessary, day and night.

On the morning of Dec. 5 his temperature was 99.4°, pulse 90, and respirations 20, and his condition was unchanged. On the 6th the spasms were of 5 seconds' duration as before, but occurred only every 2 minutes, and their severity was much less marked. The neck rigidity and trismus were unchanged, and the morning temperature was 100°. Treatment was repeated. Early on the morning of the 7th he suddenly died. The temperature had just been taken—99°.

Necropsy.—The examination was made by Capt. A. E. Wilkinson, R.A.M.C., about 6 hours after death. There were two small completely healed wounds on the left hand; rigor was noticeably more pronounced in this hand than in the right, but was absent in both arms. The right ventricle and auricle were engorged with fluid blood, while the left heart was comparatively empty. Numerous petechial haemorrhages were present in the epicardium over both auricles and ventricles. The posterior cusp of the pulmonary valve was ruptured at its free border. The remaining yalves were normal, the coronaries were patent, and the cardiac muscle appeared excellent. The lungs were pale and emphysematous, with no subpleural haemorrhages; the liver was very dark and congested; the kidneys were congested; and the brain was normal. There was a pronounced smell of paraldehyde, most noticeable in the lungs, liver, and brain. The remaining viscera appeared to be normal. The tissue from the healed wounds was not cultured for *Cl. tetani.*

Differential Diagnosis.—The diagnosis was not confirmed bacteriologically, hence the doubt expressed in the caption of this article. The other possibilities were rabies and strychnine poisoning. As regards rabies, points of similarity were the spasms and rising temperature, but the respiratory rate was only slightly increased and there was no manifestation of air hunger. The larynx was involved in the spasms, but between them speech was normal. Similarly, fluids were taken freely by mouth between the spasms. There was no hydrophobia or hypersalivation. The trismus, risus sardonicus, and constant neck and back rigidity were distinguishing features, and the incubation period of 14 days agrees with a diagnosis of tetanus arising from such a wound in the hand. Strychnine poisoning is excluded by the duration of illness (5 days) and the persisting trismus and neck and back rigidity. Poisoning by brucine has been suggested, but since this drug is similar in action to strychnine but is only slightly toxic (Lynch and Pryce, 1939), it also is excluded. Furthermore, I have been unable to find any evidence of the use of poison on arrow tips or otherwise by the natives of this district. There was no history of an arrow wound.

Comment

No other case of tetanus has been reported in this area during the eight months of British occupation. The country is dry, sandy, hot, and arid, and tetanus is rare in such soils (Boyd, 1939). However, the Italians left the site of occupation in a filthy condition, and there had been much recent contamination of the soil by horse, mule, and donkey manure. No A.T.S. had been given at the time of the injuries, the patient considering them too trivial to report. At the post-mortem examination the pronounced rigidity of the left hand was a noticeable feature. The atmospheric temperature was similar to that of a fine English spring day, and could not have appreciably accelerated the onset of rigor mortis. There was no factor in the environment which might have allowed one part to cool more quickly than another.

The man was not seen by me just before he died, so the severity of the spasms then occurring cannot be stated accurately. The nursing sepoy attending him reported that they seemed less severe than on the previous day, and that he had his back to the patient at the moment of death. The rupture of the pulmonary valve cusp was mute evidence of the immediate cause of death. It is extremely rare for a pulmonary valve cusp to rupture as a result of violent physical exertion, and there was no congenital defect in the cusp to weaken it. Death must have occurred in diastole. One can imagine that the severe respiratory effort with closed glottis forced blood out of the alveolar walls, and that the tension within the pulmonary artery was further increased by the general intrathoracic pressure's acting on its outer surface until a cusp ruptured. The emphysema in one so young is confirmatory evidence of the high pressure in the thorax at the time of death. Despite the improvement after his admission to hospital and until the moment of death, the ultimately fatal issue agrees with Cole's gloomy prognosis (Cole, 1941) in cases in which spasm begins within 48 hours of the onset of trismus.

It is admitted that tetanus usually arises from unhealed wounds or disturbed scars, but it does occur where no obvious wound can be found (the so-called "idiopathic" cases). The mere fact that the wounds in the left hand were healed does not invalidate the diagnosis.

If this was undoubtedly a case of tetanus the two protective inoculations had not even sensitized the reticulo-endothelial system, and the stimulus of toxin from the wound produced no rise of antitoxin to "the highly protective level," which has been suggested as 0.01 international unit per c.cm. (*British Medical Journal,* 1940, 2, 910). It would be similar to a persistently Schick-fast reactor. Marvell and Parish (1940) report that 26 out of 27 subjects reacted satisfactorily to the third dose of tetanus toxoid, and that the remaining titre rose from 0.05 to 0.05–0.1 unit. This, in conjunction with Perry's report, is an indication of the rarity of the case recorded above.

The occurrence of such a case vindicates the present practice of giving antitoxin to all wounded, irrespective of previous inoculation with toxoid.

I am greatly indebted to Col. J. S. K. Boyd for his criticism of this paper and personal communications upon it. I wish to thank Capt. A. E. Wilkinson, R.A.M.C., for performing and reporting upon the necropsy; Capt. G. J. H. Maud, I.M.S., Lieut.-Col. E. Oastler, R.A.M.C., and Major H. Fidler, R.A.M.C., for their criticism and advice; and the D.M.S., Middle East Forces, for his permission to publish.

Medical Memoranda

A Case of Acute Aseptic Meningitis

Acute aseptic meningitis was first described as a separate disease by Wallgren (1925). Since then numerous cases have been reported, though the cause remains obscure. It is distinct aetiologically from the virus form of lymphocytic choriomeningitis. It is often referred to as benign aseptic meningitis. The term "benign" is accurate as regards prognosis, for all cases recover; but if applied to symptoms it may be misleading, as in the present case, in which the illness was so severe that I did not at first think it could possibly be what I had always known as benign aseptic meningitis.

CASE HISTORY

I saw the patient, a girl aged 5, at her home on June 17, 1942. Two days before, she had returned from school feeling sick and complaining of sore throat: three days previously she had been perfectly fit. She had had a convulsion on the morning of the 17th She had moderate neck rigidity and a doubtful positive Kernig's sign. I admitted her as a probable case of meningococcal meningitis. On admission, lumbar puncture yielded a clear fluid under greatly increased pressure. The pupils were widely dilated and fixed: no reaction to light. Knee- and ankle-jerks were absent, as were all arm-jerks; plantars were extensor. The child resented all examination. Shortly after the lumbar puncture she had twitchings of the right side of face and body, which later spread to the left and became violent. These violent choreiform movements continued all afternoon and most of the night, and the child became desperately ill. On the assumption that this was a case of poliomyelitis, though a very unusual one, she was given 20 c.cm. of human serum intramuscularly. The following morning the movements were less pronounced, but the child was semi-comatose, with marked head retraction; her limbs were all held flexed, and it was difficult to extend them. An obvious left facial paralysis and slight left foot-drop were present, and there was some difficulty in swallowing, but the palate moved freely. She was given 20 c.cm. of poliomyelitis horse serum intravenously and 20 c.cm. intramuscularly. The facial paralysis had largely disappeared within a few hours, and by June 19 was scarcely appreciable. The foot-drop had also almost gone and there was no difficulty in swallowing. The child remained semi-conscious, with marked head retraction and fixed flexion of all limbs. The most likely diagnosis at this stage seemed to be tuberculous meningitis. On the 20th, however, there was a distinct improvement in the child's condition, and by June 22 she appeared almost normal. She was discharged on July 8, and has been seen several times since, quite fit. The following investigations were carried out:

Lumbar Puncture	Appearance of Fluid	No. and Type of Cells	Protein (mg /100 c cm.)	Chlorides (mg./100 c.cm.)	Culture
17/6/42	Clear	380 Lymphocytes, 55% Polymorphs, 40% Large hyalines, 5%	40	640*	Sterile
18/6/42	"	320. Lymphocytes, 96%	20	720	"
20/6/42	"	410. Lymphocytes, 94%	20	700	"
2/7/42	"	90 Lymphocytes, 80% Polymorphs, 20%	20	730	"

* This figure was reported as "not guaranteed" the following day it obviously supported a diagnosis of tuberculous meningitis.

Radiographs showed no skull abnormality and the lungs were clear. Animal inoculation revealed no signs of virus infection from inoculation with patient's serum or cerebrospinal fluid (June 20) Complement-fixation and neutralization tests were both negative on the patient's serum on August 17.

Comment

Points of interest are: (1) the extreme severity of the symptoms, the term "benign" being rather misleading; (2) the absence of a preceding febrile illness (in the virus form, a febrile illness of one or two weeks' duration is frequently, though not always, recorded); and (3) the very transient paralyses. The last two points are well discussed by Baird and Rivers (1938). Diagnosis from tuberculous meningitis could be made only as signs of recovery became apparent. The wild choreiform movements followed by fixed flexion of the limbs were unlike poliomyelitis, though the absence of tendon-jerks was in its favour on the first day; failure to develop any flaccidity or marked paralysis in a case in which the central nervous system was so acutely involved, and a high cell count a fortnight after the onset, suffice to exclude it.

I am greatly indebted to Dr. MacCallum of the Wellcome Research Foundation, who carried out the animal inoculation and serological tests; to Dr. May of the Emergency Pathological Service, who reported on the cerebrospinal fluid; to Dr. Sleigh Johnson, who saw the case in consultation; and to the medical officer of health, Southend-on-Sea, for permission to publish.

Thrombophlebitis of the Cavernous Sinus: Recovery

The following case of cavernous sinus thrombosis, which recovered after a combined treatment with blood transfusions and sulphathiazole, may be considered worthy of record.

Case History

On May 25, 1942, I was consulted by a vigorous, healthy married woman, aged 56, about a nasal furuncle situated inside the left alar cartilage. It was a typical staphylococcal lesion, not of large size, and there was the usual oedematous swelling of the adjacent cheek, with intense pain and slight pyrexia. I treated her from the outset with 1 tablet (0.5 g.) of sulphathiazole (M & B 760) four-hourly, and advised glycerin packs for the interior of the nose. Next day I was sent for and found a good deal more swelling of the cheek, with oedema of the lower eyelid and temperature 101°. Pus was being discharged from the furuncle. She also complained of severe supra-orbital headache, but it was not till the following day that I suspected the possibility of cavernous sinus thrombosis. On May 28 there was no longer any doubt: the left eye was proptosed, both lids being greatly swollen, and chemosis was present; the right eye was also involved, but not to the same extent. Frontal headache was very severe, and oedema extended over the supra-orbital region, more pronounced on the left side. Detailed examination of the eyes was difficult, but the patient volunteered the information that she "saw double on looking to the left," and there appeared to be definite paresis of the left external rectus—from involvement of the sixth nerve, which runs along the inner wall of the cavernous sinus. There was some rigidity of the neck muscles, and temperature had risen to 103°. The patient was seen with me by Mr. C. Gill-Carey and removed to hospital.

A blood count showed R.B.C. 4,740,000 and W.B.C. 10,200 per c.mm. A blood culture was also taken that night (from which, after five days' incubation, a *Staphylococcus aureus* was grown of the same type as that found in the nasal lesion). Immediate treatment given was a transfusion with 400 c.cm. of whole stored blood (freshly taken that day), and intramuscular injection of sulphathiazole was started, alternating with oral administration of the drug—4 g. of each within the first 24 hours. The local condition was rather worse next day, proptosis and chemosis being more noticeable; but the temperature fell gradually to normal within two days, and the general condition was obviously better. The same dosage of sulphathiazole was continued for three days, when it was reduced to 6 g., but next day the temperature began to rise, and 8 g. was again given. On June 2 there was a sharp rise of temperature to 102°, so a second transfusion of stored blood was given, once more with good effect, the temperature falling to normal next day and remaining normal for four days. There was a great improvement in the patient's condition, general and local, except for the appearance on June 6 of a papular rash on the neck, arms, legs, and abdomen As she was complaining of a good deal of nausea the sulphathiazole was reduced to 3 g. daily on June 6 and 7.

On the 7th, however, she felt very ill, with sudden rise of temperature to 102°. Again 400 c.cm. of whole blood was given, and sulphathiazole 6 g. daily. The dramatic improvement, however, was not repeated this time, so on the 9th 400 c.cm. of blood from a donor was administered. A blood count taken at the time showed W.B.C. 7,800 per c.mm., with no sign of agranulocytosis, so the dosage of sulphathiazole was stepped up to 8 g. daily. For the next four days the patient remained very ill, the rash extending into large confluent areas, and headache being severe: but the local condition of the eyes showed marked improvement. On June 13, as the rash was so distressing, and the patient had by then had 95 g. of sulphathiazole, it was decided to discontinue it. Next day the temperature remained normal for the first time for a week; the rash gradually faded and the swollen eyelids returned to normal fairly rapidly. Headache, though still severe at times, became spasmodic in character, and convalescence began.

Discussion

Thrombophlebitis of the cavernous sinus is a grave complication of suppurative lesions of the face; the mortality has been notoriously high, and all the textbooks which I consulted record that it is "almost invariably fatal." In the *Lancet* for May 2, 1931, W. G. Scott-Brown, in a comprehensive review of six fatal cases collected from the records of St. Bartholomew's Hospital, alludes to it as "an invariably fatal complication of minor facial sepsis, unless the sinus can be drained." He goes on to describe the methods of approach to the sinus: (1) the Gasserian-ganglion route; (2) the orbital route; (3) the nasal route, through the sphenoidal air sinus. But each of these represents a surgical manœuvre fraught with the gravest peril of injury to important structures and of spreading the disease to the meninges. Bischer reported in 1893 a successful case of drainage through the petrous portion of the temporal bone (Scott-Brown), but his success has apparently never been repeated.

With regard to surgical treatment of the local lesion, it is generally recognized that free incision is dangerous and apt to lead to rapid dissemination of the infection. It is therefore gratifying to feel that methods of treatment exist to-day which give a good chance of recovery. I cannot say whether the repeated blood transfusions or the sulphathiazole therapy played the greater part in curing the condition, but I feel sure that the combination of the two was the important thing. A study of the temperature chart did make it appear that the fresh antibodies provided by transfusion caused dramatic improvement on the first two occasions, and, though the temperature persisted after the third and fourth transfusions, I am inclined to think that the patient had by then had as much sulphathiazole as she could deal with. The rash was very severe, and it seems likely that the drug itself may have been responsible for keeping the temperature up at this stage, the sudden cessation of fever on discontinuing it pointing strongly in that direction.

The case has, to my mind, proved conclusively the great value of sulphathiazole in the treatment of serious staphylococcal infections, and bears out the claim of the makers that its toxicity is only half that of sulphapyridine. Before the appearance of the toxic rash my patient had had about 60 g. of the drug, and she was able to take in all 95 g. in 18 days, without serious detriment.

I am indebted to Dr. Frank Knott, pathologist to Guy's Hospital, and to Dr. J. Verdon, R.M.O. at Surbiton Hospital, for their invaluable help in treating this interesting case.

THE MEASURE OF NIGHT VISION

BY

N. BISHOP HARMAN, M.B., F.R.C.S.

It is agreed by all that in these days there should be some assortment of men and women for the various kinds of night duty according to their ability to see in a minimum of outdoor light. Those on such duty who are good observers discover for themselves some measure of their night-light reaction. An officer of the Home Guard told me that when he went out from his house at night he could see little at first, but he knew his road and walked slowly; in five minutes he could see so well that he could distinguish the white patches of road markings. There is no doubt of the truth of this observation. When I go out into the dark after an evening of reading and look at the roof of a near-by cottage it appears to have no chimney on its ridge, the skyline seems unbroken; but on looking at the gable end of the roof three metres away the missing chimney can be seen. After staying out of doors for from 5 to 10 minutes the chimney can be seen by direct fixation. The macula has recovered its full vision.

Defect of Some Night-vision Tests

There are several tests of night vision. Some are distinctly ingenious; but with some—and to my mind this is the most important point—there is no definite measure of the minimum light necessary for vision in the particular subject who is tested. Such a measure should undoubtedly be given by a direct reference to our scientific standard of candle-power, and it should be ascertained in such a way and by such an instrument and recorded in such terms that it can be obtained by any ophthalmic surgeon anywhere—here in England or far away in Australia—by repeating the same process. All our eye work is done so far as possible according to definite measurement. We agree everywhere to the measurement of Snellen's distant daylight vision test; and the figures of that test carry with them an exact appreciation of the vision of the person examined. When a workman's compensation case is under consideration in a law court the statement of the medical witness that the subject's normal eye sees 6/6 and the injured eye 6/18 conveys a direct and fair impression to the minds of the judge and the lawyers. Some definite measure and figure of night vision are equally desirable. In an article in the *Journal* on wartime street lighting[1] this was clearly stated: "The measure of illumination provided by wartime street lighting, though so small, is of appreciable benefit, especially when applied on a wide scale."[2]

A number of night-vision tests are now available. The earliest of them measured the time required by the individual to attain an adaptation to the dark. From one point of view, that of the general health and nutrition of the subject, this time reaction is valuable. But among subjects of equally good health and nutrition these adaptation tests do not give a direct and definite measure of the minimum light required by the individual to see an object or objects. An early test for the measure of night vision was that of Dr. W. D. Wright.[2] His test cards were black with a letter **C** thereon in varying shades—from pure white to dark grey. The cards were exposed to a radium glow, and examined at a distance of 12 inches. The test is simple, but it gives no definite measure of the light, for radium glow varies. Major B. W. Rycroft[3] has reversed this test for Army use, and based his instrument on a widely used form of Snellen's test. The test mark is the letter **V** painted in varying positions on transparent screens, which are illuminated from behind by an electric bulb. The test is attractive and easy to use, but again there is no definite measure of the lighting, so that the results are not exactly comparable. Opal glass varies in its filtration of light (so even does plate glass!) and electric bulbs vary in their reaction. So far as I can judge the response to this test is wholly related to the particular instrument in use at the time, and it does not give a light measure that can be obtained by anyone, anywhere, and at any time.

The Disk-spotting Test

The disk-spotting test[4] is planned on a direct measurement of light. The light is reflected from illuminated disks on a black velvet background, and the measure is gained by finding the distance at which the disks can be seen and counted. An instrument made by Theodore Hamblin is most convenient to use, but the plan of the test is so simple that it can be set up by anyone anywhere. Further, since the illumination is from "the standard candle," which is well known to all testers of lighting and all students of physics, there can be such an exactness of the light used and of its measurement that the returns of the examination are definite. The figures were given of night-vision reactions in some 700 healthy subjects with full daylight distance vision grouped as follows: (1) school children 10 to 18 years; (2) soldiers 19 to 30 years; (3) soldiers 31 to 40 years; and (4) persons over 41 years. The reactions differed slightly with age: children did the test best and subjects in group (4) least well. But there is a common average for all classes and ages which the figures showed to be 5. At a distance of 5 metres the light is only 1/1075 of a foot-candle; at 1 metre the light is 1/373, and at the greatest distance at which the disks can be counted, 8 metres, the light is only 1/1816 of a foot-candle, or 1/2000 allowing for reflection loss.

A question put to me by a colleague is one of importance. He said: "I know what is meant when the night-light reaction with this test is only 2 metres, but it would be well if there were some means of registering the reaction to this test that would be recognizable and understandable by any intelligent layman, even though he has no knowledge of how the test is made." There is, I think, a means of registering these night-vision reactions to the disk-spotting test that will meet this need. Here are the percentages of the reactions of the 700 persons examined (half-metre positions have been omitted).

Metres distant	2	3	4	5	6	7	8
% average reaction.. ..	5	12	16	21	15	4	1

The figures make it evident that night vision at 5 metres, or in light of 1/1075 candle-power, is the average for most people. If this figure 5 be taken as the denominator of a vulgar fraction of which the numerator is the reaction of the particular individual, that vulgar fraction will state the facts of the finding of the test in such fashion that any person will understand it—just as that person understands something of what 6/18 on Snellen's test implies as a fractional quantity of distant daylight vision. Returns of the disk-spotting night-vision test would be thus: 2/5, 3/5, 4/5, 5/5, 6/5, 7/5, 8/5. If, after testing a subject in this manner, the figure registered is night vision 5/5, everyone will know it is normal. If the figure is 2/5 all will know that night vision is poor; if it is 8/5 no one will doubt that it is very good.

My only criticism of such "fractional" figure returns is that they do not, and cannot, show the amazing value of the high returns. The fractions from 2/5 to 4/5 are a fair statement of the condition of the patient's night vision; but the fractions 6/5, 7/5, and 8/5 seem insufficient for the splendid condition of seeing at 6 or 7 or 8 metres. I have no doubt that in these latter cases the examiner would add a note that "the subject's night vision is exceptionally good," and the reader or examiner of the recorded returns would be duly impressed.

Griffiths, Marks, and Young have shown that the implantation of various oestrogens for periods of two to four weeks increases the insulin content of rat pancreas. H. L. Fraenkel-Conrat and his colleagues (*Proc. Soc. exp. Biol., N.Y.*, 1941, **48**, 333) confirm their observation, and believe that the effect is brought about through the mediation of the pituitary. They found that oestrogen which raises the insulin content in the pancreas of normal rats fails to do this in hypophysectomized rats. Also, implantation of the pituitaries of oestrinized rats increased the insulin content of the pancreas of the host animals, an effect not observed with implantation of pituitaries of untreated rats.

Reviews

PATHOGENESIS OF POLIOMYELITIS

Neural Mechanisms in Poliomyelitis. By Howard A. Howe, M.D., and David Bodian, Ph.D., M.D. (Pp. 234. $3.50 or 20s.) New York: The Commonwealth Fund; London: Oxford University Press. 1942.

This well-written and well-illustrated book describes the experimental work carried out by the authors to throw light upon the pathogenesis of poliomyelitis. The extent of current researches upon virus diseases is illustrated by the fact that this book contains some 200 references to this aspect of one virus infection alone. The question investigated is important because measures for the prevention of poliomyelitis can be based only upon knowledge of the mode of infection with the causative virus and the nature of the immunity which protects against a second attack. Howe and Bodian's researches suggest that the olfactory tract is probably not the usual route of infection in man, but that the virus multiplies in the alimentary canal, from which it passes to the central nervous system by ascending the axis cylinders of nerves which have not yet been identified. Within the nervous system the virus spreads along nerve paths, but there are great variations in the susceptibility of different centres. The total pathological picture is thus determined by at least three principal factors: the portal of entry, the selective spread from the region of the nervous system first invaded, and the susceptibility of the centres reached by the virus. There is evidence that immunity is not a reaction of the nervous system but is the result of protection at the portal of entry. Many problems remain unsolved, but this book is an encouraging account of steady progress made towards the eradication of this scourge of childhood.

SPECTROSCOPY OF VITAMINS AND HORMONES

The Application of Absorption Spectra to the Study of Vitamins, Hormones and Coenzymes. By R. A. Morton, D.Sc., Ph.D., F.I.C. Second edition. (Pp. 226. 28s. 6d. post free inland.) London: Adam Hilger, Ltd.

The great advance in the technique and applications of spectroscopy during the last ten years has made it imperative that Dr. Morton's book should be completely rewritten and enlarged. Spectroscopy has become widely used not only for detecting the presence of many substances but also for determining them quantitatively in many media. In particular the estimation of certain vitamins and hormones has been much simplified by this branch of physical chemistry. Full details of the procedures and precautions necessary for such determinations are given in the second edition of Dr. Morton's book. In addition he has also given a satisfying account of the theory underlying the technique. The substances to which the science of spectroscopy has been most usefully applied are the steroids (provitamins D and vitamins D, oestrogens, follicular hormones, male hormones, etc.), the carotenoids and vitamin A (with a full examination of the conversion factor for changing intensity of absorption at 325 mμ into international units of biological activity, and the conclusion that one molecule of carotene yields only one molecule of vitamin A), vitamin E and antioxidants, vitamin K, vitamins C and P, the vitamin B complex (a pity that pantothenic acid was omitted from the summary on page 140), purine and pyrimidine derivatives, proteins, enzymes and coenzymes. The physiological aspects of these substances are treated shortly but adequately to interest the pure spectroscopist. The book contains both name and subject indexes. The diagrams, plates, and whole format of the book are excellent.

DEVELOPMENT OF THE CEREBRAL CORTEX

The Postnatal Development of the Human Cerebral Cortex. By J. LeRoy Conel. Volume II: The Cortex of the One-month Infant. (Pp. 144; 108 plates. $8.00 or 46s. 6d.) Cambridge, Massachusetts: Harvard University Press; London: Oxford University Press. 1941.

The second volume of this work by Prof. J. LeRoy Conel has now been published, and it maintains the high standard of the first volume, which deals with the cortex of the newborn infant. Precisely the same procedures have been adopted, so that the two series of observations can be compared side by side—namely, the cortex of the newborn babe with that of a one-month infant. Some results of these observations, which indicate the number and measurements in μ of the cells in each unit and the width of the laminae in the various areas of the isocortex, have been tabulated, so that changes in the different areas of the isocortex that take place during a given period of development may be compared, and, with the photomicrographs and camera-lucida drawings of individual neurons in each area, be used as a standard for comparison of the normal structure of the cortex at the ages investigated, when dealing with physiological problems or morbid material. Later stages in the growth and differentiation of the cortex are to be described in subsequent issues of the series. The procedures adopted in the preparation of the sections comprise staining with cresyl-violet, Cajal, Golgi-Cox, and Weigert methods; and the criteria used in studying the development of the cortex include size of cell bodies; chromophil substance; neurofibrils; size and length of cell processes; branching of axons, spines, thorns, and varicosities; size and number of exogenous fibres; and myelination.

One specific purpose which the author has had in planning this and subsequent instalments of his work is the observation and record of those changes that occur during the growth and differentiation of the cortex which are correlated with the development of the progressive phases of behaviour in growing children. During the first month of post-natal life definite advances, although as yet slight, have been greatest in the growth of those parts of the cortex which are associated with movements of the hands, and the co-ordinated movements of the eyes which are necessary for binocular and stereoscopic vision. We note also that, while in the one-month infant the greatest advance in the growth of cell processes, Nissl bodies, and neurofibrils is in the large pyramidal cells of layer V of the posterior part of G. frontalis medius, the functional area for contralateral movements of the eyeball, the posterior region (pars opercularis) of G. frontalis, Broca's area for speech, shows little advance. The receptive area of the parietal lobe and the "striate area" of the occipital lobe have advanced in development to a greater degree than the acoustic or hippocampal areas, in which progress is only slight. It will be interesting to learn from the later volumes of this work whether in the period corresponding to increased growth of the legs, and the use of the lower limbs in walking, there will be a corresponding change in the motor cortex of the leg area, and also whether there will be a perceptible advance in the development of the acoustic and Broca's areas, preceding or at the time when the child learns to speak.

Notes on Books

A fourth edition has now reached this country of Dr. MALFORD W. THEWLIS's book, *The Care of the Aged* (*Geriatrics*) (Henry Kimpton; 35s.). The third edition was noticed in these columns as recently as April 4, 1942, when we commended it as a book of reference relating to old age and its diseases which might well find a place on the shelves of all general physicians. The text has been revised and additional matter included. The importance of the subject continues to grow because of the great shift in living population of the United States and of this country. The latest census figures show that there are nearly nine million persons in the U.S.A. over 65 years of age—an increase of 35% for this age group since 1930, while the total population increased by no more than 7.2%.

The ninety-ninth edition of the *Medical Directory* has been published by Messrs. J. and A. Churchill, Ltd. It appears in the same form as last year and at the same price. There has been a net increase of 1,346 entries, and the number of pages of text has been increased by thirty-two. The numerical summary of the medical profession shows that there are now 66,740 names, compared with 65,394 in 1942. Increases will be found in all but one of the sections of the *Directory*: 24 in London, 719 under Provinces, 114 under Abroad, 380 under Scotland, 179 under Ireland, and 2 under Wales. A decrease of 72 is recorded under Services. The figures do not include 1,632 temporarily registered practitioners whose names, addresses, and qualifications are listed in a short section near the end of the volume. The publishers are to be congratulated on keeping this valuable book of reference up to its usual high standard.

Dorothy Gill (*Arch. Pediat.*, 1942, 52, 587) has collected 36 cases of nephritis following varicella, including one of her own in a boy aged 5½. The ages ranged from 6 months to 11 years. Of the 26 cases in which the sex was mentioned, 10 were males and 16 females. The interval between the eruption and the onset of nephritis varied from 1 to 24 days. Seven of the cases were fatal.

TREATMENT OF CANCER OF THE LARYNX

The curative or radical treatment of malignant tumours must at present take the form of either excision or irradiation, and as the surgery of malignant disease has always been from its very nature fraught with disaster and disappointment, however great its positive achievements in various directions, the hopes aroused by the claims of radiotherapy have produced a swing towards this treatment even for operable cases of cancer. It is this group of cases, which might have been successfully treated by excision, that have provided radiotherapy with almost the whole of its good results, though it has had some success in inoperable cases. This, however, has eventually proved nearly always to be palliative only.

As the two forms of treatment follow quite different routes, and attempts to combine them have led nowhere, it is very difficult, and perhaps impossible, to obtain an unbiased judgment on their respective merits. To gain the experience and skill required in order to obtain the best results in any group of cases much patience and long years of training are necessary, whether it be in surgery or in radiotherapy, and this must induce some bias, however resolutely the tendency be resisted. It is an odd coincidence that the most determined attacks have been made by radiotherapy on regions usually in the province of specialists where the results of excision have been fairly good, while regions which fall to the general surgeons have been relatively neglected. Thus the uterus, larynx, and pharynx are favourite fields for radiotherapy, though excision has much to offer, whereas the stomach, colon, rectum, and breast are less subjected to this treatment. Without inquiring more closely into this, it remains clear that generally the cases most favourable for surgery are those most favourable for radiotherapy, and those unfavourable for the one, such as cases of cancer of the oesophagus, are also unfavourable for the other. Unfortunately the two methods, apart from palliative treatment, are not complementary, and where one fails—speaking quite generally—the other fails also. This is shown very well by the case of cancer of the larynx, where both surgery and radiotherapy can, up to a point, advance quite respectable claims, and their respective advantages have been debated now for many years.

A good instance of this kind of disputation is a recent paper by Nielsen and Strandberg[1] from the Finsen Institute in Copenhagen, where the art of radiotherapy has reached the peak of perfection. The results, therefore, must now be about as good as it is possible to achieve. Although the authors appear to be unaware of the fact, intrinsic cancer of the larynx is relatively uncommon in the Scandinavian countries, as compared, for example, with Great Britain, while the incidence in the upper jaw is greater. This accounts for the rather small size of their material, amounting to only 63 cases, though this is compensated by the careful study and records of the cases. They were all treated by protracted fractional irradiation with *x* rays, sometimes for as long as eight weeks, but recently for about three to four weeks, the total dose being 5,000 to 6,000 *r*, and occasionally 7,000 *r*. The authors state that perichondritis and necrosis have not been seen except in cases in which the cancer had already invaded the cartilage before treatment was instituted. There have been no late cutaneous changes of any severity. The sites of origin in these cases were three: (1) the true vocal cords; (2) the vestibule, which includes the false vocal cords, the laryngeal surface of the epiglottis, and the sinus of Morgagni; (3) the subglottic region. The authors state that "the cases most amenable to radiation therapy are absolutely those in which the mobility of the vocal cord is still unimpaired, or nearly so." Tumours of the ventricular bands and the immediate neighbourhood—that is, those in Group 2—are considered to be particularly radiosensitive.

In order to evaluate the results of treatment the cases were grouped into the following stages: (1) Those operable by laryngofissure: the carcinoma is localized to the anterior two-thirds of one vocal cord, which retains free mobility. (2) The carcinoma involves the anterior commissure and the anterior portion of both vocal cords, whose mobility is free or only slightly impaired. (3) Cases operable by laryngectomy or possibly hemilaryngectomy: the muscles are invaded and the cord fixed with possibly subglottic extension. Also subglottic cancers without enlarged lymphatic glands. (4) Cases with extension beyond the limits of the larynx. All patients with enlarged lymphatic glands are included in this group, and also carcinomas of the vestibule and extensive subglottic tumours. Cases in which the patient was over 70 were regarded as "biologically inoperable." There were 6 patients in Stage 1: these all remained well with a normal voice, 3 of them for more than 3 years and 1 for 5 years. There were 8 patients in Stage 2: these all remained well, but 3 of them for less than a year. In Stage 3 there were 21 patients, of whom 11 would have been operable by laryngectomy: of these none has survived 5 years, 3 for 3 years, and 8 for 1 year or less; the fate of the remaining 10 out of the 21 is not made clear. There were 28 inoperable cases in Stage 4: no patient has survived for 5 years, but 3 are alive after 3 years and 5 for lesser periods.

The authors complicate the report of their results, as is seen in almost every radiological report, by including cases which have been treated for less than 3 years. No surgeon would report a recent case unless for some exceptional reason, and would certainly never report a series under 3 and preferably not under 5 years. To report cases under 1 year is, however, an established radiological custom, and the condition of these recently treated cases is generally described as encouraging, which may be the case if encouragement is required, but they vitiate the statistics. This is shown by the fact that some of the cases in the above record were afterwards submitted to operation with survival for several years. Not only is it impossible to accept the standards of operability and inoperability proposed by the authors, especially in the matters of palpable lymphatic glands, encroachments on the pharynx, and perichondritis, but they fail to take account of improvements in surgical technique corresponding to improvements in radiological technique. The operation of laryngofissure gives at least 80% of freedom from recurrence for 5 years with very little disability, and the same may be said of modified excisions falling upon both cords, except that the voice is not so good though quite strong. At least 40% of those submitted to laryngectomy, even with a liberal view of its limitations, survive for 5 years, though many needing this operation have enlarged glands in the neck. With modern technique the disability is not very great, and a useful voice is obtained or a speaking instrument can be used, but the mutilation is serious compared with the result of a successful treatment by radiotherapy. It may, however, be much less so than the result of a radiotherapeutic failure.

---

[1] *Acta radiol.*, 1942, **23**, 189, 255.

It appears, therefore, that as an adequate operation is available for every stage of the disease which presents any prospect of benefit from radiotherapy, surgical treatment should be considered first, and radiotherapy adopted only if for some reason surgical treatment is contraindicated. These authors, however, would reverse this usually accepted procedure. They propose a test irradiation to discover how the tumour reacts. "If it reacts without local complications, during the first part of the irradiation, there is good hope that by continued treatment with full dose freedom from symptoms may be obtained." This compromise is unlikely to be generally acceptable, though it is often put into practice with uncomfortable results for both patient and surgeon, and a decision upon one or other line of treatment should be made in the beginning. This paper shows yet again that it is in the more advanced cases, in which laryngectomy, especially with the extensions of which it is capable, frequently succeeds, that radiotherapy fails except as a palliative, and this should influence the decision. The fallacy of biological inoperability at the age of 70 is shown by the case of a man aged 78 who had an extrinsic carcinoma of the larynx with enlarged glands in the neck. The glands in the neck, part of the pharynx, and part of the larynx were excised by lateral pharyngotomy. He succumbed recently to an apoplexy, having had no recurrence.

BYSSINOSIS AND BAGASSOSIS

Dangerous dusts in industry are mostly mineral, but there are two lung diseases produced by the inhalation of dusts of vegetable origin. Byssinosis is the name given to a disease in cotton operatives which has been the subject of several investigations in this country, and is now scheduled under the Workmen's Compensation Act. Its mode of production is still somewhat obscure, and it would be interesting to know whether the findings in a recent investigation in the United States have any bearing on it. There being a large cotton surplus in that country, needy rural families were provided free with enough for making mattresses, of which 3,944,456, as well as other articles, were made during 1940-1 at rural mattress-making centres. Large numbers of people so engaged developed within a few hours a transitory illness consisting of fever, headache, nausea, and vomiting, but without symptoms referable to the respiratory tract except a dry cough and a sense of discomfort or pressure in the chest. This illness was associated with the handling of a low-grade very dusty cotton; carding it and beating the filled mattresses to level them raised much dust, and the inhalation of this was clearly the cause of the illness. All the incriminated cotton was also stained, having a yellow or brown colour. P. A. Neal, R. Schneiter, and Barbara H. Caminita[1] describe an investigation which has brought the cause of this illness to light. Neither chemical nor mycological examination of dust from the stained cotton revealed anything significant; the abnormality was found to be bacterial. In the stained fibre were large numbers of bacilli, and cultivation of the dust showed the presence of many millions per gramme of a capsulated motile Gram-negative bacillus which was not found in cotton of good quality. The same micro-organism was recovered from the dust of a cotton mill in which "mill fever" had occurred some time earlier. Extracts of stained cotton dust and filtrates of cultures of the cotton bacterium produced inflammatory lesions when injected intradermally, and reproduced the full picture of the mattress-makers' disease when sprayed and inhaled by human volunteers. When the dust itself was inhaled and the disease produced, it did not appear that the cotton bacterium multiplied in the air passages. These and other experiments in a very thorough investigation seem to have established fully that this disease is due to the absorption of a bacterial toxin from inhaled dust.

Although this episode in the U.S.A. is exceptional, the possible relation between this disease and the "mill fever" or "Monday fever" of cotton operatives seems well worth investigation. These authors point out that the Departmental Committee on Dust in Card Rooms in the Cotton Industry[2] refers in its report to the presence of large numbers of Gram-negative bacilli in cotton dust, but considered them of no importance because such bacilli could not be found in the operatives' sputum. If such bacteria are responsible for any of the symptoms complained of by cotton operatives generally, the present American work fully explains why they should not be recoverable from the secretions of an affected person. "Monday fever" is a condition for which a bacterial intoxication affords a reasonable explanation; whether long repetition of this form of insult to the bronchial mucosa can be expected to give rise to the chronic bronchitis and emphysema which constitute byssinosis is another matter. It should certainly be worth while to reinvestigate respiratory disease in cotton workers from this new point of view.

Bagassosis is the term suggested in their recent paper in this *Journal*[3] by L. I. M. Castleden and J. L. Hamilton-Paterson for a somewhat similar condition, in that the dust producing it is also of vegetable origin. Bagasse is the fibre left after extracting the sugar from sugar-cane: board made from it is a good insulator, both auditory and thermal. Dry crushing of bagasse liberates much fine dust, and workers exposed to it developed after two to four months increasing dyspnoea, with severe cough and scanty sometimes blood-stained sputum; there is slight fever, and the *x*-ray picture is that of a bronchopneumonia Complete recovery followed removal from the dusty atmosphere in two of their cases, but in two others and in further cases described by J. A. Gillison and F. Taylor[4] there was disability of longer standing, and some degree of pulmonary fibrosis may have been produced. No bacterial cause was found, either in dust or in sputum, but the patients had a cutaneous sensitivity to bagasse extract which was not found in controls. This is evidently a more severe and much more rapidly disabling condition than byssinosis, and is presumably a reaction to some chemical constituent of the fibre concerned.

STARVATION IN EUROPE

When the time comes for relief in Europe the Allied nations will be united in a Herculean task. The work must be carefully prepared beforehand, and plans are already engaging the attention of many persons and official committees. The first and most urgent requirement will be the provision of food and shelter for the starving, the refugees, and the destitute. Then will come medical care of the sick, reorganization of the social and medical services, and the setting into motion of agriculture and industry. For all this planning there must be a headquarters staff, under which the technique of relief and its specialist problems will have to be worked out in detail by *ad hoc* committees from among Allied representatives. The administrative capacity and pooled resources of the world will be taxed to the utmost. Medicine has an important part to play in this humane work of relief, and what it can do is now being discussed. Doctors and nurses, it is obvious, will be wanted for medical relief. The planning and carrying out of nutrition schemes; measures for the control of typhus, malaria, enteric; the danger of the present continent-wide increase in tuberculosis—these are but some of the tasks for international medicine in the post-war period. But can anything be done now for the appalling famine in Greece, Belgium, Spain, Poland, Yugoslavia, and Western Russia? It is estimated that the present surviving population of Greece is some 6½ million and that the wheat now available, excluding imports permitted by the belligerents, would keep alive about 3½ million of them. In Athens 100,000 out of 1,000,000 have already perished. The plight of the Greek children is terrible. Even in December, 1941, the Athens Welfare Centre stated that 9 out of 10 babies were dying in the first six months because their mothers were starved and milk was almost non-existent, practically all the cattle having been slaughtered during the famine. The need to send milk for the children is urgent, and 100 tons of Canadian powdered milk are to be carried by Swedish ships and distributed by the International Red Cross, in addition to the monthly supply under navicerts of 15,000 tons of wheat. The first cargo of powdered milk has been dispatched, but it is not yet known whether it has reached its destination. Vitamins and powdered milk in much larger quantities and dried vegetables are essential to save lives and to counter an epidemic of nutritional disease of osteomalacic type which has developed in both children and adults. Here are some observations from eyewitnesses in Athens: " . . . The children had not even the strength to beg, and some had died as they crouched over a grating; they seemed to be asleep, and hours might pass before their companions realized they were dead" (January, 1942). "Orphans and abandoned children are found wandering in the streets . . . starving, dirty, pale, and thin, a sight recalling Dante. They stop at nothing to find a bit to eat, searching among refuse and fighting the dogs for something edible . . ." (March, 1942). The morbidity rate is such that in June, 1942, there were four children to a bed in one temporary hospital. Conditions are little better in Belgium. The infant mortality rate is rising steeply and is said to be now about four times as high as in 1939; famine oedema is seen and vitamin deficiency is common. The morbidity from tuberculosis has increased 30 to 80% in different parts of Belgium. In varying degrees of severity the same appalling conditions prevail in other European countries.

The sending of food to any occupied country has political implications which make relief out of the question unless guarantees can be given and accepted that the food will not be used by the enemy. And even if it is not used directly by the enemy it may be of use to him indirectly by sparing his own supplies to the country he occupies. But now that arrangements have been made to distribute cargoes of wheat and dried milk in Greece, our own Government should soon know if the distribution is satisfactory; it will then be easier to determine what further help can be given to the starving population, and especially the children, of Belgium. The Famine Relief Committee (67, Brook Street, London, W.1) has estimated the quantities of dried milk and vitamins (per million inhabitants) needed to save the lives of children in Greece and Belgium. These calculations can be applied to other countries. For Greece the tonnage of shipping per month is 2,000, and the Swedish Foreign Minister has stated the willingness of Sweden to carry relief.

In the armed Forces medical men treat the sick and the wounded prisoner with as much care as they treat their own men. In so far as it is compatible with the paramount task of winning the war, the relief of that pathetic casualty of war—the child ill from starvation—is an especial object of medical concern.

COMBINED TUBERCULIN AND RADIOLOGICAL SURVEY

In 1934 the Royal College of Physicians of London inaugurated under the terms of the Prophit Bequest a survey scheme with the following objects:

> To determine the level of tuberculous infection by the graduated Mantoux tuberculin test.
>
> To correlate the result of the Mantoux test with the results of *x*-ray examination of the thorax.
>
> To determine the value of mass *x*-ray examination as a means of revealing unsuspected pulmonary tuberculosis.
>
> To assess the possible prognostic significance of the Mantoux test.
>
> To discover the existence and importance of opportunities for primary tuberculous infection in the population studied.
>
> To determine the significance of certain abnormal appearances in the chest *x*-ray which are not yet fully understood.

This was a highly ambitious programme. An illustration of the difficulties met with in carrying out radiological and tuberculin surveys in this country is the fact that only now has the first communication[1]—and that a preliminary one—appeared on the work of this survey. Results are given of the tuberculin testing and *x*-ray examination of five groups of people, mostly between 15 and 25 years old: a volunteer control group of 1,543 persons (considered to be non-representative of London's average population, as the proportion of factory workers was small, and only a very small proportion came from overcrowded homes), 784 "contacts," 953 voluntary hospital and 523 municipal hospital nurses, 1,247 medical students, and 918 boys entering Royal Navy training establishments. The chief radiological findings at first examination are of much interest. In the control group only 0.13% were found to have pulmonary tuberculosis requiring treatment; an additional 0.71% were found to have inactive pulmonary tuberculosis. Healed primary lesions (that is, calcified foci of the primary complex) were detected in 7.2%. (This figure has little significance, because many such foci would not be discovered without routine over-penetrated and lateral radiographs.) In the contact group the first two percentages given above were respectively 2.4 and 2.5 (over 18 times as many active lesions). Among the hospital nurses active phthisis was found in 0.2% and inactive in 0.4% more. Among the medical students none was found to be suffering from active phthisis, and only 0.19% had inactive lesions.

The conclusions drawn from the results of tuberculin testing must be accepted with caution. International Standard, synthetic, medium, old tuberculin was used. The tests were read "after 48 to 72 hours," and the minimum positive reaction—apparently for all dilutions of tuberculin used—was taken as "2 mm. of definite oedema with surrounding erythema" (it is not stated how much erythema). Apart from the difficulty that must surely be met with in measuring "2 mm. of definite oedema" and distinguishing it from the needle puncture, it would be of interest to know on the basis of what work these criteria were adopted as sufficient to exclude false reactions. Using O.T., the following minimum criteria have been adopted by well-known workers in this field: D'Arcy Hart,[2] erythema or erythematous infiltration 5 mm. in diameter (Hart used a control test of broth in addition); Opie and McPhedran,[3] Wallgren,[4] Ustvedt,[5] Söderling,[6] Kayne,[7] 10 mm. erythema with infiltration. It will be agreed that the synthetic medium tuberculin is "purer," but even in connexion with this the State Serum-Institute at Copenhagen, on the basis of extensive and careful work by Holm,[8] recommends[9] the following as the minimum requirements for a positive reaction: a "papule" of 7 mm. at 48 hours and 5 mm. at 72 hours in the first test and of 10 mm. (48 hours) and 8 mm. (72 hours) in the second and third tests. Even with the still purer PPD, Aronson and his co-workers at the Henry Phipps Institute[10] regard the minimum for a positive reaction as "some redness and definite oedema more than 5 mm." Thus it would appear that the results given in the Prophit survey publication cannot be considered altogether reliable in regard either to the incidence of tuberculin-negative persons in the different groups or to the proportion that react to the different strengths of tuberculin. For instance, a simple calculation shows that no less than 90% of the tuberculin-positive controls are said to have reacted to 1 in 10,000 tuberculin, a high figure indeed when contrasted with 61% to 68% in different age groups found by D'Arcy Hart,[2] and 50% to 68% by Madsen and Holm.[11] Nor can the conclusions be accepted in regard to increase or decrease in sensitivity in repeat tests after an interval. Our final comment is this. Dr. Ridehalgh finds that, among the controls aged 15 to 30, 7.5% were tuberculin-negative; among the hospital nurses, 11.5% (voluntary) and 17.8% (municipal); and among the boys aged 15–16 in naval training, 34.0% and 21.3%, depending on the proportion coming from rural districts. It is safe to say that these percentages are actually higher by an unknown amount, and therefore that an appreciable percentage of individuals reach adult life even in towns without being primarily infected.

SURGERY OF OESOPHAGEAL CANCER

In 1913 Torek performed the first successful operation for total excision of the oesophagus for carcinoma; this brilliant achievement was further enhanced by the patient's surviving for eleven years without recurrence; during this time the distal end of the oesophagus in the neck was connected to the gastrostomy by a rubber tube, and in this way a good state of nutrition was maintained. The promise that Torek's operation held out was not to be easily fulfilled, and malignant disease of the oesophagus has continued to be the surgeon's despair. Indeed Ochsner and De Bakey in a recent review[12] state that out of a total of 53 additional recorded cases 41 of the patients (70.6%) have died. No doubt one reason for the slow progress, in addition to the complexity of the problem, was the absence of wide experience in intrathoracic surgery. The recent rapid development of the surgery of the thorax has directed attention anew to the problem of partial or total extirpation of the oesophagus, and, slowly but surely, much new ground is being gained.

Ohsawa's[13] report from Kyoto in 1933 of 8 successful cases of resection of the cardia and lower end of the oesophagus with immediate restoration of continuity passed almost unnoticed, and it was not until Adams and Phemister[14] published (from America) in 1938 a successful case of resection of the lower oesophagus with immediate oesophago-gastrostomy that interest became fully aroused; since then at least a dozen other such cases have been recorded in the U.S.A. and several more complete oesophagectomies. Experimental investigations have also been made into methods of resection, suture, and restoration or reconstruction of continuity. Carter, Stevenson, and Abbott,[15] for example, have shown that implantation methods of joining oesophagus to stomach are followed by stenosis, and that direct mucosal apposition is necessary. Improved methods of anterior oesophagoplasty are described by Stephens[16] in a recent review of 23 cases submitted to operation. Carter, Abbott, and Hanlon[17] record their use of tubes made from the greater curvature in restoring continuity. Much of this experimental surgery is of a high order and of great interest, even though the methods described may not be finally accepted. The main difficulty in reconstruction of a new anterior oesophagus is in securing sound union between skin and stomach: fistulae readily form, and the best way to avoid this is by using an inferior oesophagostomy as advocated by Garlock, Wookey, and Phemister. Unfortunately this cannot often be done, but when possible it is a simple manœuvre, and the oesophageal mucosa and the skin tube take much more kindly to union than stomach and skin. Phemister[18] reports 12 cases of excision with 8 immediate survivals; Wu and Loucks,[19] writing from Peking, record 11 cases with 8 survivals, in 5 of which continuity was restored at once by direct oesophago gastrostomy.

It is interesting to compare these American experiences with work just recorded in this country. Allison[20] writes from Leeds of four patients who survived the operation but unfortunately died of recurrence within a year Franklin, from Prof. Grey Turner's clinic at Hammersmith, describes two cases of total oesophagectomy: one of his patients died 16 months later from metastases; the other is still alive and well after 18 months. Prof. Grey Turner has done much to keep alive surgical interest in carcinoma of the oesophagus in this country and has refused to admit that the problem is insoluble. His well known case of success by the "pull-through" method was a milestone in the surgery of this condition, although it is in essence a "trick" that can scarcely be expected to supplant the direct approach through open thoracotomy Finally, Brock[21] records the first case from this country, in fact from Europe, of resection of a tumour of the cardia involving the lower end of the oesophagus with immediate direct oesophago-gastrostomy by a combined abdomino-thoracic operation.

Perusal of all these papers impresses one with the difficulties and problems that have to be faced in those cases of total extirpation in which an anterior oesophagus has to be reconstructed. When oesophago-gastrostomy can be performed both patient and surgeon are spared much extra anxiety and operating. There seems every reason to strive to achieve this in all cases of carcinoma of the lower part of the oesophagus in which total oesophagectomy seems unnecessary on pathological grounds, as the main spread of the metastases is downwards to the glands along the lesser curvature. The recurrence rate is discouraging, but this is a common experience in the early attempts at surgery of malignant disease of any organ and should be a spur, not a deterrent, to effort: Torek's original patient survived 11 years without recurrence.

REINSTATEMENT REFUSED AFTER WAR SERVICE

CASE OF LEICESTERSHIRE POLICE SURGEON

The Government has frequently declared that men who have served with the Forces should not be penalized with regard to employment on their return to civil life. Private employers have been exhorted to recognize this principle, but they have a right to expect that official bodies and local authorities will set the example. An instance of what appears to be a flouting of this principle has occurred in the case of a standing joint committee in dealing with a police surgeon. The police authority in each county is a standing joint committee, which is composed of representatives of the county council and Quarter Sessions. It may be that its double derivation is considered to give it some right to override ordinary standards of procedure by which both its parent bodies would feel themselves bound, but the facts are extraordinary enough to warrant public attention. If the facts available are not all the facts, and other reasons in the background have operated, the standing joint committee can hardly complain, because its response to repeated requests by the aggrieved person and those acting for him is the autocratic utterance, "We do not give our reasons."

At the outbreak of the war Dr. Justin Davies, who held the appointment of surgeon to the Leicester County Police, was called up as a Territorial medical officer for military duties. He gave to the chief constable the name of a deputy to act during his absence, but the chief constable, according to Dr. Davies, suggested that he should resign his post temporarily, which he did, and a few days later it was intimated to him that another doctor had been appointed to take over his duties. After about twelve months Dr. Davies relinquished his commission on the ground of ill-health, returned to his practice, and notified the chief constable, who, however, informed him that the doctor who had been appointed to take over the duties in his absence had been confirmed in his appointment. No reply was received to his request for the reasons for his supersession, and when he asked for an interview with the chairman or with the committee he was refused. Later, at the request of the Local Medical War Committee, the police surgeon who had been acting in Dr. Davies's absence submitted his resignation, and, following the usual procedure when a practitioner acts as deputy, paid into the Protection of Practices Bureau half the fees he had received during his tenure of the office. The standing joint committee accepted the resignation of the deputy, but some months later its clerk informed the Local Medical War Committee that the erstwhile deputy had been reappointed, with his partner to act with him, "in succession to Dr. Justin Davies, whose appointment was determined some time ago." Incidentally the partner was away, serving with the Army. When Dr. Davies joined up for military duty his temporary resignation was asked for, and yet the standing joint committee appoints as one of his successors a practitioner who is already in the Army.

Repeated letters have passed between the Local and Central Medical War Committees and the clerk to the standing joint committee in an endeavour to ascertain from the latter why Dr. Davies was not reinstated on his return from active service. The invariable reply is: "It is not the [standing joint] committee's custom to give any reason for any decision at which they may arrive." Equally unsatisfactory has been the correspondence with the Under-Secretary of State for the Home Office. Three months elapsed before an official of the Home Office replied that the appointment of a police surgeon was a matter for the police authority and did not require Home Office approval, but the Secretary of State had made inquiries of the Leicestershire Standing Joint Committee, which was "not prepared to give their reasons for not reappointing Dr. Davies." Apparently the standing joint committee was as high-handed with the Home Office as it had been with the Local Medical War Committee. It never gives its reasons, even for disregarding, *prima facie*, the requests of the Government to reinstate men on their return from Service, and Whitehall is reduced to impotence by the feudalism of Leicestershire.

There the matter rests, but it is an uneasy rest. Here is a medical man who temporarily relinquished an appointment solely because of his absence with the Forces. On his return he is refused reinstatement by a public body, which declines to give its reasons. If there are reasons which justify terminating Dr. Davies's appointment, the practitioner and those acting on his behalf have the right, as an ordinary principle of English justice, to be informed of them. If there are no reasons, the action of the Standing Joint Committee for Leicestershire will cause widespread disquiet among those who, relying on the assurance that their jobs, big or little, whole-time or part-time, would be available on their return, have gone cheerfully to serve their country. If county councils and standing joint committees and bodies of that description cannot act fairly in such a matter, what can be expected of the ordinary tradesman, to whom it may mean personal sacrifice? It is a question of principle far more important than the loss to this practitioner of a part-time appointment. It cuts across the common rights of aggrieved persons and appears to flout the undertaking of the Government which, by implication, extends to local authorities.

It may be that the standing joint committee had in mind the dictum of Lord Mansfield: "Never give your reasons, for your judgment will probably be right; but your reasons will certainly be wrong." But whether in this case the judgment is right or wrong is past finding out save behind the shut doors—shut even to the aggrieved person—of the Standing Joint Committee for Leicestershire.

ELECTROMEDICAL APPARATUS AND ELECTRIC PADS AND BLANKETS

The Board of Trade and Ministry of Supply have consulted the Ministry of Health regarding future production (in the United Kingdom) of electromedical apparatus and electric blankets and pads. War demands upon man-power and the increasing and inevitable shortage of raw materials render it imperative that production be controlled and limited to the minimum essential requirements and, also, that available supplies shall be procurable only for clearly established medical needs. Agreement has been reached on future control measures.

Measures for Control

Henceforth raw material will be released only for the production of electromedical apparatus of major importance in medical treatment and for the purpose of treatment which cannot be carried out by alternative means involving less use of labour and materials Apparatus of a luxury type or constructed to a luxury standard will no longer be available after existing stocks are exhausted, and no material will in future be released for the production of equipment which has not a clearly accepted and defined medical value.

Under the Machinery, Plant, and Appliances (Control) (No. 3) Order, 1942 (S.R. & O. 1942, No. 2487) (price 2d.), manufacturers may supply apparatus of an electromedical nature to members of the public only where a licence under the Order has been obtained from the Board of Trade. The purchaser must obtain the licence and the Board of Trade will require applications to be supported by a medical certificate setting out detailed particulars of the apparatus required, the condition for which its use in treatment is required, and certifying that the patient is unable to make use of hospitals, clinics, or other existing facilities. The applications will be referred to the Ministry of Health for confirmation that the designated apparatus is essential for the particular condition. Application forms may be obtained from Industrial Supplies Department (Machinery Licences Division), Board of Trade, 1-6, Tavistock Square, London, W.C.1.

Manufacturers licensed by the Board of Trade under the Electrical Appliances (Control of Manufacture and Supply) Order, 1942 (S.R. & O. 1942, No. 1453) (price 1d.), for the manufacture and supply of electrical heating pads and blankets may supply such pads and blankets to members of the public only in those cases where a certificate from a registered medical practitioner, to the effect that such supply is essential on medical grounds, has been submitted and the written approval of the Board of Trade, acting in consultation with the Ministry of Health, has been given for the supply. Applications for licences for electric blankets and pads should be addressed to the Board of Trade, Imperial Chemical House, Millbank, S W.1

Supplies to hospitals and similar institutions will be regulated by the issue of licences by the Board of Trade, but, while it is hoped to meet reasonable requests, strict scrutiny of applications will be necessary.

Care in Issue of Medical Certificates

Medical practitioners will realize that the serious limitation of production which will now be imposed renders it essential, in the interests of the really necessitous cases, that the most careful consideration and discrimination should be exercised in the issue of certificates, which should be given only where the need is absolutely imperative and alternative treatment is not practicable. Only with the full understanding and co-operation of the medical profession will it be possible to safeguard the essential needs of patients without prejudice to the vital national needs for man-power and material

NEW YEAR HONOURS

The names of the following members of the medical profession were included in a New Year Honours List published in *Supplements* to the *London Gazette* on Jan. 1 and 4:

Barony

Sir Charles McMoran Wilson, M.C., M D President of the Royal College of Physicians of London.

G.B E. (Civil Division)

Sir Henry Hallett Dale, C B.E , M.D , D.Sc., F R.C.P. Lately Director of the National Institute for Medical Research. President of the Royal Society.

K.C B. (Civil Division)

Sir (William) Wilson Jameson, M.D , LL.D., F R.C.P., D P H. Chief Medical Officer of the Ministry of Health and Board of Education.

K.B.E. (Military Division)

Henry Letheby Tidy, M.D., F R.C.P. Hon Major-Gen., late R.A.M.C.

Knighthood

Ratnajoti Saravanamuttu, M.B., C.M For public services in Ceylon

C.B. (Military Division)

John Alexander Manifold, D.S.O., M.D., D.P.H. Major-Gen., late R.A.M.C. Honorary Physician to the King.

C.S.I.

Heerajee Jehangir Manockjee Cursetjee, D.S.O , B Chir Major-Gen., I M.S. Honorary Surgeon to the King. Deputy Director of Medical Services, Headquarters, North-Western Army

C.M G.

Edgar Laurent, M D. For public services in Mauritius.

C.I.E.

Edward Cotter, M.B., B.Ch., D.P.H. Lieut.-Col., I.M.S Public Health Commissioner with the Government of India

C.V.O.

Charles Sculthorpe Morris, M.R.C.S., L.R C.P., L.D.S.

C.B.E. (Civil Division)

Wallace Ruddell Aykroyd, M.D., Sc.D. Director, Nutrition Research Laboratories, Coonoor, S. India.

Frederick Hall, M D , D.P.H. Medical Officer of Health to the Lancashire County Council. For services to Civil Defence

Hon. Capt. Rai Bahadur Maharaj Krishna Kapur, L.M.S., D P.H Medical practitioner, Lahore, Punjab.

William Paterson Hay Lightbody, L.R C P.&S Ed., D P.H. Colonial Medical Service. Director of Medical Services, Sierra Leone.

John Bowes McDougall, M.D.Glasg., F.R.C.P.Ed Medical Director of Preston Hall, Maidstone.

M.V.O. (4th Class)

John Robert Kennedy, M.B., C.M.

O.B.E. (Military Division)

Justin Wilfrid Francis Albuquerque, M.B., B.S , D P H Lieut.-Col., I.M S.

Everett Francis Crutchlow. Temp. Acting Surg. Lieut.-Cmdr , R.C.N.V.R.

Frederick McKibbin, M.B., B.Ch Lieut.-Col (temp. Col), R.A.M.C.

David Mitchell Wallace, F.R.C.S. Acting Wing Cmdr , R.A.F.V.R.

Edward Rex Pascoe Williams, M.B , B.S. Surg Cmdr., R N

O B.E. (Civil Division)

Alfred Innes Cox, M.R.C.S , L.R C.P. Lieut -Col., I.M.S. District Medical Officer and Superintendent, Government Headquarters Hospital, Ootacamund, Madras.

Hugh Gregan Crawford, M.C., M.R C.S., L R.C.P. For services to the Boy Scout Movement in Staffordshire

David Montague de Silva, M.R C.S., L.R.C.P., D.P.H. Air Raid Precautions Controller, Ceylon.

James Dunlop, M B., Ch.B. Medical Officer for Civil Defence, Glasgow.

John Gilmour, F.R.C.S.Ed., D.P.H Regional Medical Officer, Department of Health for Scotland.

William Muir Howells, M B., Ch.B., D.P.H Colonial Medical Service. Deputy Director of Medical Services, Gold Coast

Mohammed Husnain, F.R C S.Ed., D.L O., D.O.M.S. Professor of Ophthalmology and Oto-rhino-laryngology, Prince of Wales Medical College, Patna, Bihar.

Madhav Krishna Kelavkar, M.B.E., M.B., B.S. Lieut.-Col., I.M.S. Assistant Director-General, Indian Medical Service (Stores)

Bernard Moiser, M.B., D.P.H. Leprologist to the Government of Southern Rhodesia and medical officer in charge of the Leper Settlement near Fort Victoria, Southern Rhodesia.

Charles Robert Philip, M.B.E., M.D. Colonial Medical Service Medical Officer, Kenya.

Henry Sacco, M.D. For public services in Malta.

Alfred Tennyson Smith, M.D. County Commissioner, St. John Ambulance Brigade, Hampshire and Isle of Wight. For services to civil defence

Prof Vittore Vassallo, M.D. Superintendent, Hospital for Mental Diseases, Malta.

M.B.E. (Military Division)

Narayan Vishwanath Karve, M.B., B.S. Capt., I.M.S.

James Leslie McCallum, M.R.C.S., L.R.C P. Capt. (temp Major), I.M.S.

Desmond Alan Dill Montgomery, M.B , B.Ch. Capt , R.A.M.C.

Frederick Grace Smith. Major, Ceylon Medical Corps

Ram Lall Soota, M B., B S. Capt., I.M S.

John Anderson Strong, M B , B.Ch. Capt., R.A.M.C

M.B E. (Civil Division)

Alexander Innes, F.R C S. Medical Officer in charge of the Surgical Division, Calderstones Emergency Hospital, Lancashire.

Pierre Ange Antoin Rostant, M B , Ch.B. Colonial Medical Service. Medical Officer (Surgeon), Trinidad.

Miss Margaret Sophia Sharp, M.B Centre Organizer for Bradford County Borough Women's Voluntary Services for civil defence.

Hon. M.B E. (Civil Division)

Dr. Moshe Wallach Principal of the Shaarei Zedek Hospital. Palestine.

PREVENTION OF CRIPPLING

The following statement has been issued by the Joint Standing Committee of the Empire Rheumatism Council and the British Orthopaedic Association, the chairman and vice-chairman of which are respectively Lord Horder and Mr G. R Girdlestone·

1. The Empire Rheumatism Council and the British Orthopaedic Association are in cordial agreement that their mutual co-operation in the diagnosis, prevention, and treatment of crippling conditions will be of the greatest service to the health of the community.

2. Both bodies aim at close liaison between the physician specializing in rheumatism and the orthopaedic surgeon, seeking to enlist the sympathetic co-operation of the general practitioner, the public health services, and social workers generally.

3. Orthopaedic hospitals and orthopaedic departments of general hospitals should include on their staffs a physician with special knowledge of the rheumatic diseases.

4. Rheumatism centres should include on their medical staffs an orthopaedic surgeon.

5. Since the application of methods of physical therapy and of occupational therapy for orthopaedic and rheumatic patients is largely identical, a joint out-patient clinic should, wherever practicable, serve for both classes of patients. In such joint centres the orthopaedic cases will be under a team headed by an orthopaedic surgeon; for rheumatic cases the team will be headed by a physician

6. In view of the growing appreciation of the regionalization of medical services the scheme for rheumatism centres should be planned to fit into such schemes as may be arranged for the future This has, in fact, already largely been done in orthopaedic schemes.

7. As in orthopaedic work the development of successful centres has been based upon the legal requirements of the notification of certain crippling diseases and upon the public responsibility for the provision and payment for their treatment, so in rheumatic disease a similar degree of responsibility should be assumed by the State or local authority.

8. Adequate provision for the training of young physicians and surgeons in research, diagnosis, and treatment should be associated with suitable encouragement to make the study of rheumatic disease a life-work.

9. To put into effect the agreed plan of co-operation, a Joint Standing Advisory Committee should be constituted of equal, or nearly equal, numbers of representatives of both organizations, with a secretariat of two, one from each organization.

The Standing Advisory Committee includes, in addition to the chairman and vice-chairman, Dr. Hugh Burt (acting for Lieut.-Col W. S. C. Copeman), Mr. Norman Capener, Mr. W. A. Cochrane, Squadron Leader W. D Coltart, Prof. L. S P. Davidson, Mr. A. G Timbrell Fisher, Mr. S. L. Higgs, Brig-Gen. F. D. Howitt, Prof H. J. Seddon Joint Secretaries—Mr. Norman Capener and Sir Frank Fox

Reports of Societies

INFLUENCE OF DIET DURING PREGNANCY

At a recent meeting of the Scottish Group of the Nutrition Society held at Edinburgh University the subject for discussion was the influence of diet during pregnancy on (*a*) the health of the mother, (*b*) the growth and viability of the foetus, and (*c*) the post-natal development of the offspring.

Prof. R. C. **GARRY**, who presided, pointed out that rational treatment of many of the disturbances of pregnancy must wait on a fuller understanding of maternal and foetal physiology during pregnancy. Although a physiological process, pregnancy was of necessity a strain on the maternal organism, and latent defects in the mother might become patent at this time. Unfortunately, too, pregnancy imposed an economic and physical strain on the mother and the entire family, which it should be the duty of a satisfactory social system to alleviate.

Prof. A. St. G. **HUGGETT**, discussing the part played by the placenta in foetal nutrition, said the placenta was a secretory, a storage, a transfusion, and an endocrine organ, reaching its maximum development comparatively early in pregnancy; 70% of the final weight of the human foetus was laid down in the last three months of pregnancy, when placental growth was at a standstill or even showing regression. Transmission of material across the placenta was controlled by factors as yet little understood. In experimental animals, restriction of carbohydrate intake in the mother's diet caused a fall in maternal liver glycogen while leaving the foetal liver glycogen uninfluenced. On the other hand, the administration of excess carbohydrate to the mother only slightly raised the glycogen content of the maternal liver, while the glycogen in the foetal liver increased markedly. Yet during all these changes the glycogen content of the placenta remained practically unchanged.

Vitamins, Calcium, and Iron

Dr. H. M. **SINCLAIR**, who reviewed the evidence for nutritional deficiency during pregnancy, said there were indications that supplementary feeding of vitamins A and D lowered the incidence of puerperal sepsis, but it was doubtful if the action was specific. There were conflicting reports on the importance of the vitamin B complex in preventing the toxaemias of pregnancy, gestational polyneuritis, and Wernicke's encephalopathy. Claims for the efficacy of vitamin E in the prevention of abortion had still to be substantiated, and it was not known if vitamin C and/or K played any part in preventing accidental haemorrhage during pregnancy and excessive bleeding at parturition. Epithelial hyperplasia of the gums was not uncommon in pregnancy, but did not yield to vitamin C therapy. There was evidence that this condition was due to excessive quantities of oestrogens in the tissues. Iron-deficiency anaemia was common during pregnancy, but the physiological hydraemia of pregnancy must be taken into account in assessing the severity of the condition. The demands of the foetus for calcium, particularly during the last months, were large and undoubtedly depleted the maternal reserves. Nevertheless, supplementary feeding of calcium must not be indulged in lightly, since it might prolong pregnancy and harden the foetal skull.

Prof. **DUGALD BAIRD** showed that stillbirths and neonatal deaths were more common in hospital practice than in specialist practice, 3.3% as against 0.6%. Since the standard of medical and nursing care in the two groups was practically the same, the social status, with its different dietetic background, was probably the operative factor. The same factor was possibly the cause of a greater percentage of premature labours in hospital maternity practice—9 as against 2 in specialist practice. On the standard of the League of Nations Technical Commission the diet of pregnant women was frequently defective, and evidence was accumulating that raising the diet to this standard decreased the incidence of prematurity and lowered the rate of stillbirth.

Mr. W. **GODDEN** said that stillbirths and neonatal deaths were only too common in farm practice, and there was little doubt that they were due to dietary deficiencies. There must be an adequate supply of energy, of protein, and of calcium and phosphorus. Iron deficiency, especially in the breeding sow, did not affect fertility but adversely affected viability during the suckling period. An adequate supply of vitamins A and D was essential for successful pregnancy in cattle, sheep, and pigs; the evidence concerning the vitamin B complex was equivocal, and there was no definite evidence that vitamin E deficiency occurred in mammals other than the rat.

Dr. I. **LEITCH** (Rowett Research Institute) discussing the incidence of stillbirths and neonatal deaths in England and Wales, in Scotland, and in New Zealand, said there was obviously something wrong with Scotland, with a figure of 80 per 1,000 total births as against 66 for England and Wales and 51 for New Zealand.

ADRENAL NEUROBLASTOMA

At the last meeting of the Section of Pathology of the Royal Academy of Medicine in Ireland, with the president, Dr. M. H. **O'CONNOR**, in the chair, Dr. A. **THOMPSON** described a case of neuroblastoma of the adrenal medulla. The patient, a girl aged 6 years, was admitted to hospital suffering apparently from an intracranial condition. She died twenty-four hours after admission. On admission she was in a state of very grave collapse, bleeding from the eyes, nose, and bowel. There was considerable protrusion of the eyes. Dr. Thompson had thought at first that the case might be one of chloroma because of the prominence of the eyes and the very severe degree of anaemia. Post-mortem examination showed a neuroblastoma of the right adrenal gland. The tumour was about the size of a billiard ball. According to the literature these cases were highly malignant, and the primary tumour usually did not attain a size large enough for palpation before the patient died.

Dr. **O'CONNOR** said that the striking feature of these tumours was the lymphatic spread. Dr. **THOMPSON**, in reply, said that no cerebral metastases had been found post mortem. The case had started as an unexplained anaemia and the child had been in hospital in the country for some weeks before her eyes had started to protrude.

At a recent meeting of the Maternity and Child Welfare Group of the Society of Medical Officers of Health, with the president, Dr. **CATHERINE MORRIS JONES**, in the chair, an interesting experiment—namely, the establishment within the boundaries of a factory of an ante-natal and gynaecological clinic—was described by Dr. L. B **BOURNE**, medical officer to the factory, and Mr. J. V. **O'SULLIVAN**, consultant to the works clinic. The clinic is in premises outside the workshops, and can be visited by women unknown to their fellow workers, and an appointment system prevents waste of time. The medical staff, by their knowledge of a woman's state of health, are able to modify her working hours immediately when necessary. Mr. O'Sullivan commented on the continued good health of most of the women, who carried on their work up to a late stage of pregnancy Fatigue was more usually due to the strain of shopping and to home duties in addition to the factory work, rather than to the factory work itself. Both speakers claimed that the experiment had already justified itself in lessened absenteeism and improved team-work. The clinic was very popular among the women who used it, and the extension of the idea to other areas was worth consideration by the authorities.

MERSEYSIDE HOSPITALS COUNCIL

The latest report of the Merseyside Hospitals Council announces a record income for 1941: employees' contributions came to £229,805, an improvement of some £36,000 on the year before, and employers' contributions to £52,721, an increase of £6,500. On the other hand, Hospital Sunday collections, subscriptions, donations, and the proceeds of special efforts were heavily down. In 1941 the Council came yet nearer to that state of affairs when it will pay 20s. in the pound to the hospitals for their services to its contributors. During the year £134,253 was distributed to 24 associated voluntary hospitals, together with £30,623 out of the balance brought forward from the previous year. A sum of £16,136 was paid to the medical staffs fund Twenty-one other voluntary medical institutions received £11,246, municipal hospitals £30,893, and civic charities £22,506 This last item follows upon an agreement during wartime that one-half the yield of the extra penny which was introduced should go to the war funds of the Lord Mayor of Liverpool and the civic heads of the other Merseyside local authorities. Of the post-war hospital position the report says that Merseyside hospital planning is considerably ahead of that of many areas. Merseyside "is ready geared to play its part in the co-operative effort which the Government contemplates for after the war."

Correspondence

Pasteurization of Milk

SIR,—In your leading article (Dec. 19, p. 727) the writer says: "By pasteurization we mean, it should be clear, the freeing of milk from pathogenic micro-organisms that might infect the consumer." Most people define pasteurization as the raising of milk to 150–160° F. for 20 minutes. The large retailers of milk pasteurize it on the day of collection in order that it may not be bad on the day of delivery—it is a commercial proposition, is it not?

Is not the real crux of the matter whether pasteurization kills tubercle bacilli? In my opinion and experience it does not. I am really appalled by the number of cases of active tuberculosis I see in abdominal glands at operation. I have gone into the matter carefully, and found that many of these cases have consumed pasteurized milk only. I am even more appalled by the number of *x*-ray films I see showing evidence of tuberculosis of the mesenteric glands. I now advise my patients to give their children T.T. milk or boiled milk only.

The writer of your article is entitled to believe in pasteurization, but he is not entitled to think that those who do not cannot think straight. Every problem has two sides, and what is right to-day is wrong to-morrow (*vide* the treatment of fractures by skin-tight plasters).—I am, etc.,

Rotherham ERIC COLDREY.

⁂ That in some instances tubercle bacilli are present in so-called pasteurized milk is an argument not against pasteurization but against inadequate pasteurization.—ED. *B.M.J.*

SIR,—In your leading article entitled "Do Doctors disagree about Pasteurization?" (Dec. 19, p. 727) there are points, I think, which should be followed. To begin with, Is raw milk better for the child than pasteurized milk? Sir Frederic Still on Dec. 28, 1938, wrote me: "I think in several ways raw milk is to be preferred to pasteurized milk if only we could exclude infection in raw milk." A county medical officer on July 24, 1932, wrote: "I have been consistently in favour of raw milk despite the almost insuperable difficulty of always getting milk of sufficiently clean quality."

The infant mortality in Toronto, where all milk is pasteurized, is double that in Victoria, Vancouver, where all milk is drunk raw. My own statistics dealing with large masses of children for 18 years show raw milk to be a good thing. At least one-third of these children, and all infants and toddlers, were on T.T. milk.

I have pointed out before that the credit does not lie wholly on raw milk The credit must be shared with the excellent health services of the L.C.C. and other counties, and their extra milk for school children and the plain hot dinners. These clinics were my right hand in my fight against death and disease.

It is said that of cows reacting to the tuberculin test only 22% give tuberculous milk, and that of the human tuberculosis population only 5% suffer from bovine tuberculosis. How, then, does T.B. get into milk? Largely through dung and dust, as does 99% of other pathological germs. Abortus and streptococcus can be eliminated, as they come direct from the cow.

W. S. Forbes in the *Journal* of March 24, 1934, says: "The only public health consideration is not pasteurizing but production of clean milk." We would then not have the taking of unmeasured doses of bacteria as an oral vaccine, but one under control.

Now a word about epidemics There is a tendency to lay too much stress on epidemics. They are accidental, like the water-borne typhoid outbreaks. I wonder how many practitioners have had cases due to *Brucella abortus*. In my 18 years among children I have had one; in 12 years of private practice none. To say these cases were not recognized won't do, for to do so casts reflection on our teaching schools—a continued fever leads to a blood test, and more often than not it is typhoid or malaria; not often is it abortus infection.—I am, etc.,

Eastbourne. A. H. MACDONALD.

SIR,—The leading article (Dec. 19, p. 727) asking the question, "Do doctors disagree about pasteurization?" showed up your *Journal* at its worst, and must have disgusted many readers. It was a nasty, totally irrelevant article, full of an ill-conceived and spurious cynicism, written by someone whose mentality was divorced from the basic aims which, even to-day, thank God, animate the minds and the ideals of the majority of our profession. Sir Henry Morris-Jones and his colleagues have put before His Majesty's Government a resolution based upon the highest principles which should actuate our profession, principles at which your leader writer sneers—namely, those which will lead to the ultimate prevention of a terrible disease.

No one in his sane senses would allow "typhoid bacilli to appear in the household drinking-water as a method of immunizing the susceptible population against enteric fever," but, as described in the same issue of your *Journal* (p. 719), Dr. R. J. Peters and Dr. D. H. Clutterbuck did not make an attempt to eliminate typhoid fever from Glasgow by pasteurizing the drinking-water of the affected area; they eliminated the source of the infection, and cleansed a butcher's shop where the motto was not apparently that "cleanliness was next to godliness." Helpful as antiseptics and sulphonamides may be, it is not by the use of these but by excision of dirty wounds that we have been able to save thousands of lives, thus getting rid of the dirt before it can do further mischief.

Pasteurization is right so long as you, Sir, are prepared to forget that tuberculous-infected cattle can be got rid of, that byres, milkers, and dairies can be kept clean; that cows' teats can be cleaned, and that the homes of our dairy workers can be made fit for human beings to live in and not the wretched huts in which we see our farm workers live, and which would shame, in many cases, an Indian's wigwam. If an Easter Ross farmer sold a bull for three thousand guineas for transport to the Argentine that bull would not be allowed to enter the Argentine did it possess the slightest taint of tuberculosis, but that same bull, at a much reduced price, would be allowed to live in this country and spread among our folk all the disease, misery, and pestilence which you, Sir, of all people, should use every ounce of your energy to get rid of; and you are satisfied to think that the cows which it would infect would have their milk pasteurized instead of the bull having its throat cut.

The elimination of infected cattle is not impossible if the powers that be had the guts to insist that it should be done, nor is it impossible to have clean byres, clean milkers, clean dairies, and decent homes for our farm workers; but it is you who believe "the world to be flat" if you think that it is pasteurization which is to remove the evils of which you write. If you wish to get a cart up hill put the horse in front, not behind; advocate getting rid of the root cause of this evil, and do not try, even with the help of Prof. Selby Wilson, to mislead the public that we are doing all when we are doing nothing. If you are in real difficulty call in to your help Sir William Beveridge or Lord Cooper. These men seem to have the knack of getting at the root of our economic problems; I think it would take either of them little time to get the worm out of the core of this evil. Their methods reach beyond the self-interested.—I am, etc.,

Tain. E. K. MACKENZIE.

SIR,—The majority of your readers will wonder still more at your moderation in the leading article (Dec. 19, p. 727) regarding this question. It seems almost incredible that two such responsible members of the profession should publicly disagree with the accepted views of the profession on this important matter.

If Sir Henry Morris-Jones were conversant with the legislation that has been in force in the Province of Ontario Canada, forbidding the sale of milk which has not been pasteurized, he would discover that surgical tuberculosis has been gradually eradicated from the Province. Prof. Gallie, professor of surgery in Toronto University, informed me in 1938 that he rarely saw cases of surgical tuberculosis in his wards or practice and that he considered that the enforced pasteurization of all milk for human consumption was responsible for this remarkable achievement. This was confirmed by many other authorities in Canada whom I interrogated.

It is well known that tuberculin-tested herds cannot be relied upon to produce milk free from tubercle bacilli, for the simple reason that cows acquire the disease in the intervals between the tests and therefore contaminate the milk from the herd. Milk even from tuberculin-tested herds, therefore, should be pasteurized, as it is the only reliable safeguard. Fortunately, all the large wholesale distributors of milk safeguard themselves and the public by pasteurization.

Dr. A. H. Macdonald is evidently not acquainted with the accepted theories regarding "immunity."

Legislation on this question is long overdue, and the sooner this question is definitely settled the better. Cows' milk, from any source, should be forbidden for human consumption unless it has been pasteurized. Economics and politics should not be considered when the health of the community can be safeguarded by such simple means.

I visualize in the future the invention of a wonderful machine in which grass will be put in at one end and milk will be extracted at the other. This will have one advantage, I trust, and that is it will be free of all germs, but I have doubts about its epicurean value. In the meantime let us proceed with compulsory pasteurization.—I am, etc.,

"BOVINE."

Control of Venereal Diseases

SIR,—Quotations divorced from their context are always misleading, so Dr. E. W. Assinder's doubts expressed in your issue of Dec. 19 (p. 740) as to the accuracy of my statement that "there is not the same sense of shame with regard to V.D. in Scandinavia as there is in this country" is not wholly surprising. I would be truly distressed if it were thought that my comments were directed against the ideals and mode of life in the Scandinavian countries. On the contrary, my admiration is so great that I constantly speak of their very real democracy, social conditions, and advanced medical standards with profound respect tinged with envy.

What I tried to say, no doubt ineptly, was that the Scandinavian attitude towards sex differed from that of the conventional Anglo-Saxon in being more forthright. For example, in more than one V.D. clinic women nurses staffed the male clinics, arranged irrigation apparatus, and so on, and in one electrical department (not connected with a V.D. clinic) I saw two women and one man lying under the one lamp for lupus treatment, with respectively neck, arm, and leg exposed. I believe that either of these conditions of work or treatment would be unusual in a British hospital; though given sufficiently true *pudor* as opposed to mere prudishness, there is nothing but what is natural in either situation. My impression was that, especially in Sweden, the desire to be healthy was so strong that treatment for V.D. was taken eagerly when required so as to re-establish health.

I have many times had to deal with the sense of shame of married women infected by their husbands, a shame so profound that they dislike the very thought of attending a V.D. clinic lest they feel further degraded by "having to sit with such women as are sure to come there." A very great deal of time, patience, and persuasion has often to be spent in women's clinics to get such married women to attend because of this deep-rooted elemental feeling. They have to be educated in the clinic so as to change that feeling for the constructive wish for health and freedom from infection.

Alongside this desire for health one would wish that in young people of both sexes self-respect and the ideal of continence could be inculcated by precept and example. But "false shame" is a deterrent to clinic attendance, and is in the end anti-social, leading too often to cessation of treatment when relief of symptoms has been obtained, without persistence till complete freedom from infection is secured.—I am, etc.,

London, W.1. MARGARET RORKE.

SIR,—Defence Regulation 33B is a move in the right direction, but I doubt if it will carry us very far. I have had many years' experience in the treatment of venereal diseases as surgeon in charge of several clinics, and it has always been my endeavour to get contacts under control. Several methods are employed, the chief being that of sending a note by the patient to the contact explaining the situation and asking him or her to attend the clinic for examination and treatment if found necessary. What is the result? We are told: the name and address of the contact are unknown; the contact cannot be found or has left the district; the note has been delivered but the contact refuses to attend; when the name and address have been given and a note posted it is returned marked "Name unknown" or "Gone away"; when a health visitor has called she finds that the wrong address has been given; she is often refused admission, or, when admitted, receives an indignant denial that he or she is involved. A few attend.

Several years ago I opened a discussion before the Society of Medical Officers of Health on the subject of the desirability of making venereal diseases notifiable and treatment compulsory. I stressed the point that there would be no publicity and that only those who refused to be treated or those who defaulted would be affected by the law. The opinion expressed was that it would drive V.D. underground and do more harm than good. The subject is difficult, but now, with so many of the population in the public services and under control legislation should be easier.—I am, etc.,

Hampstead, N.W.3 HAMISH NICOL, F.R.C.S

Preparation of the Hands for Operation

SIR,—When I did my surgical dressing in the old Royal Infirmary at Newcastle-upon-Tyne in 1896 gloves were not used and the surgeons relied entirely on the antiseptic technique Rutherford Morison was most particular, and tried out all the known methods of hand preparation. At that time he recognized the importance of smooth skin, and every night in life rubbed his hands all over with glycerin. His favourite antiseptic for the hands and the skin of the patient was 1 in 1,000 perchloride of mercury in watery solution. This always made my own hands desquamate, but I subsequently discovered that I could use 1 in 1,000 biniodide of mercury year in year out without producing any roughness. Morison's results in wound healing were wonderful. I have never seen better, but in addition to hand preparation he was most careful and punctilious about all the details of wound management. Nonetheless he did have runs of mild infection for which we could not account. About 1904, when I was assisting him regularly, we began to use the thick, heavy rubber gloves so largely employed by the French surgeons up to recent times. These were not boiled but sterilized by long soaking in antiseptic solution. Soon after the adoption of the thin rubber gloves, about 1906, boiling became the usual method of sterilization

Only those surgeons who have operated without gloves and with soft marine sponges instead of gauze swabs can have enjoyed the pure delight of operating. But I should be sorry to have to do without gloves because, since their adoption, satisfactory wound healing has been more uniform, and they are the best protection against infection of the surgeon's hands. If we must do without gloves it is more than ever important to take care of the hands by avoiding all unnecessary risks of contamination both in our work and socially (the late Prof. Garre of Bonn lamented that he could not help his wife in the garden because he had to put his hands in his pockets to keep them clean!). We must also keep the hands smooth. For antiseptics to be efficient they must soak into the surface skin, the nails, etc., and it takes some time and repeated use of chemical antiseptics for these structures to remain saturated. In the pre-glove days we used to notice that it was after the surgeon's holidays when he had been away from antiseptics for some weeks that he was most often annoyed by outbreaks of mild infection among his wounds.—I am, etc.,

British Postgraduate Medical School G. GREY TURNER.

Erythroblastosis Foetalis

SIR,—For the reasons given in his letter (Dec. 19, p. 738) I would support Dr. Herbert Levy's suggestion that the title "haemolytic disease of the newborn" is an even better and more accurate substitute for "erythroblastosis foetalis" than "haemolytic anaemia of the newborn," and I hope that this title will be universally adopted.

I am familiar with both the types of bone lesions mentioned by Dr. Levy. The first, in which the long bones show, as described by Follis *et al.* (1942), zones of increased and decreased density, occurred in one of my patients who suffered from congenital haemolytic anaemia, and who, in spite of treatment, remained anaemic until her death at the age of 8 months. A description of the *x*-ray appearances of this child's long bones, together with excellent illustrations, has been put on record by my colleague Dr. Teall (1939).

The other type of bone disease (osteitis fibrosa disseminata, or polyostic fibrodysplasia) was the particular form of bone change to which I referred when I wrote of the "ghastly sequelae" of haemolytic disease of the newborn. This sequel was first described by my colleague Dr. Frances Braid (1932), although this fact seems to be completely overlooked by most of the writers on the subject. In 1938, in a letter to the *Lancet* commenting on a paper by Robson and Todd (1938), I pressed Dr. Braid's claim for priority, and at the same time reported another case which was then under my own care. In 1940 Dr. Braid wrote a further paper having the title "Osseous Dystrophy following Icterus Gravis Neonatorum, Generalized Osteitis Fibrosa with Areas of Pigmentation of the Skin and Precocious Puberty in the Female," in which she included a full description of my patient. In the recent contribution by Falconer and Cope (1942) Dr. Braid's second paper is discussed, but there is not any reference to her first paper. Although the paper of Albright and his colleagues did not appear until 1937, Falconer and Cope refer to this condition as Albright's disease and do not accept it as a sequel of icterus gravis, although on the basis of 4 out of 27 cases showing this combination they do think, as stated by Dr. Levy, that "its frequency seems to admit more than a chance association."

I agree with Dr. Levy that since haemolytic disease of the newborn may occur without jaundice some examples of the association between it and this form of bone disease may have been overlooked; furthermore, unless this possible association is borne in mind inquiries into the patient's past history may not be as thorough as is desirable.—I am, etc.,

Birmingham LEONARD G. PARSONS.

High Flying for Whoopers

Sir,—If, as seems possible, the success of this treatment (*Journal*, Dec. 26, p. 758) and that of exposure to a low-pressure chamber is due, as it may be, to want of oxygen by the infecting agent, exposure to partly de-oxygenated air may be equally effective; this is as easy to apply as is oxygen treatment. A cylinder of nitrogen with 10% oxygen can be obtained, and the mixture allowed to flow into a simple form of breathing mask.—I am, etc.,

Chalfont St Peter LEONARD HILL

The Dysentery Carrier

Sir,—I note that attention is gradually, if somewhat belatedly, being focused on the subject of dysentery in this country as though it were a newcomer. In actual fact bacillary dysentery—as well as malaria—was once rife here, and a state of residual endemicity may be found to-day in many rural areas. Its propagation is not by any means entirely due to carriers, and it may easily be acquired by townspeople in the course of an afternoon's picnic in an infected area or by eating uncooked salads grown on land manured by human excreta. I had several cases of the latter kind two years ago, all traced to their source. Only a few years ago the medical officer of health of a large rural district denied its prevalence in his area until I proved it both by culture and agglutination to his reluctant satisfaction. He described it as "epidemic diarrhoea."

I have no doubt whatever that the intractable disease known as chronic ulcerative colitis usually begins as an unrecognized acute bacillary dysentery, which, in the absence of efficient early treatment, develops into the resistant and often fatal condition with which many of us are familiar ("Ulcerative Colitis: What is it?" H. M. Stanley Turner, *Guy's Hosp. Gaz.*, 1936.) Why the ulcers should fail to heal and why certain cases should assume all the characters of chronic ulcerative colitis is another matter. It possibly depends on several factors, of which secondary infection and a failure to assimilate the small amount of vitamins (? B complex and C) contained in a necessarily restricted diet may be two.

Prof. Gustav Singer (Dec. 26, p. 765) is right, of course, to stress the need for sigmoidoscopy. It is often possible in bacillary dysentery to obtain positive swabs from the bases of ulcers even after repeated negative stool cultures.

I think the important thing is for general practitioners in this country to realize that acute bacillary dysentery is a disease which must be included in the pathological repertoire of this country and is not a monopoly of the tropical practitioner; that stool cultures are likely to be negative if specimens are transmitted to the laboratory by post unless emulsified with glycerin–saline; and that specimens should be taken as early as possible in the disease and preferably be transmitted at once by hand and kept warm in transit.

There are many villages where it is said that "diarrhoea goes through the village" once or twice a year and where on inquiry it will be found that a large proportion of cases show the distinctive syndrome of colic, frequent stools, passage of blood and mucus, and tenesmus. In such villages the prevailing type of conservancy is the earth closet and the defective domestic well in close proximity.—I am, etc.,

Brookwood, Surrey H. M. STANLEY TURNER.

Sir,—With reference to the letters of Dr. Ian Taylor (Nov. 21, p. 618) and Prof. Gustav Singer (Dec. 26, p. 765) may I report some experiences on the spread of dysentery during and after the last war. In a great number of post-mortem examinations I have observed that dysentery bacilli, even of the less virulent Flexner group, were often found in the patients' mesocolic glands, although the patients died of causes other than dysentery. Previously I had reported that occasionally the bacilli could be found in the blood and in the urine of a dysentery patient. It was important, as in the case of cerebrospinal meningitis, that the material should be examined as fresh as possible and be kept at body temperature. We always endeavoured to take it from the lesion as recommended by Singer, but it is not necessary to do it with a speculum, and the results are equally superior to the examination of the stools if simple swabs are taken from the rectum and plated out immediately. In a recent case the pathologist followed this suggestion, and immediately obtained a Sonne bacillus in a small epidemic where the routine examination of other cases had given negative results.

It was assumed that, apart from direct contact by bacilli carriers or dysentery cases, flies might transfer the germs from faeces and other infected material on to food. In pre-war times great care was rightly taken in many countries to prevent food from being contaminated by touch—both of shop assistants and customers—or by flies. Nobody was allowed to touch food in shops, and this was prevented either by wrapping the food (bread, biscuits, etc.) in transparent paper or by placing it under glass protection, which also prevented contamination by droplets (T.b!). Shop assistants were instructed not to handle food which was to be eaten without previous cooking—e.g., butter, cheese, ham, etc.—but to use instruments—forks, knives, and forceps. If proper supervision and a warning would be given to the food shops and to the public, I feel sure that the number of dysentery cases could be greatly reduced. I would further recommend wire netting or muslin of narrow mesh for protection against flies.—I am, etc.,

Buxton E. M. FRAENKEL

Joint Committee on Rheumatism and Orthopaedics

Sir,—The article in the *Times* of Dec. 29 giving notice of the formation of a Joint Standing Advisory Committee of the Empire Rheumatism Council and British Orthopaedic Association is one to be welcomed. Some wheels turn slowly, others, especially in wartime, fast.

The annotation in the *Journal* of April 26, 1941 (p. 633), called for just this kind of collaboration between orthopaedists and, for want of a better name, rheumatologists. Subsequent correspondence was anything but laudatory, especially from the orthopaedic group. Have they changed their "spots"? If so this is good news. Or are they dissenting among themselves? We notice, however, that there is no recognition or official representation on this advisory committee of the British Red Cross Clinic for Rheumatism, the pioneers of the movement

It is true that two of the members (one "acting for") of this committee are also physicians at the clinic in peacetime, but they are not on this committee representing the Red Cross. We also note that they say the committee "should be constituted of equal, or nearly equal, numbers of representatives of both organizations." The committee consists of 14 members, 8 of whom hold the F.R.C.S., and 5 medical qualifications rather than surgical. This is nearly a two to one representation.—We are, etc.,

Tetanus

SIR,—I was interested in Dr. Leslie Cole's article on tetanus (Nov. 7, p. 550) and in the letter of Dr. J. H. Hannan (Nov. 21, p. 619). I thought the following case unusual and of sufficient interest to merit publication.

The patient, a healthy male of 58 years, consulted me in April, 1940, complaining of stiffness in the neck. After 7 days he developed tetanus with clonic spasms. There was a history of his pricking his thumb some weeks previously while planting rose trees, but no injury or foreign body could be detected. A.T.S. 200,000 units was given intravenously and recovery was rapid. Three weeks later he developed acute retention due to an enlarged prostate, and a de Pezzer catheter was introduced. Prostatectomy was not performed until Sept., 1940, as his general condition was poor.

On Oct. 12 he complained of stiffness in the jaws, and gradually this become generalized and eventually he got clonic spasms. It was not until Dec. 14 that I repeated serum. This time I gave it by the intramuscular route in small repeated doses until I had given 100,000 units. There was a good improvement in 48 hours, but it was several weeks before the tonic spasm had disappeared. The patient returned again in Oct., 1941, complaining of stiffness of the jaws, which developed into typical tetanus with clonic spasms. I repeated 100,000 units A.T.S. intramuscularly in gradually increasing doses and he was fully recovered in 14 days. I then laid open the suspected thumb and removed a thorn. Since then the patient has remained well.

This case completely disproves Dr. Hannan's idea of trusting to the body forming antiserum. It would also point to the advisability of giving serum in doubtful wounds and of not trusting to active immunization.—I am, etc.,

Larne, Co. Antrim. HUGH WILSON.

Stilboestrol in Cancer

SIR,—I thank Dr. J. A. Vaughan (Dec. 19, p. 737) for drawing attention to my letter in the *Journal* of July 27, 1940. She ought to know that the patient referred to therein ultimately died. His was a well-advanced case, and as the tablets of stilboestrol caused nausea he refused further medication. There is no doubt, however, about the rapid retrogression in the size of the growth. I believe I was rather timid about dosage and that larger amounts should be administered by the intramuscular route.

Briefly, I consider that what happens in the genesis of cancer is this: there is overactivity of the anterior pituitary with excessive secretion of the gonadotrophic hormone, which is offset by the production of oestrin, there being a physiological antagonism between the two. Indeed it is very likely that when the amount of oestrin reaches peak level it inhibits altogether for the time being further secretion of the pituitary hormone. After middle life, when the generative organs fail, the ovary no longer responds to the whip of the gonadotrophic hormone and there is little or no oestrin to restrain the activities of this. It thus finds other cells to respond to its stimulation—namely, the young and perhaps immature cells of some tissue which is continually being replaced as the result of prolonged irritation. These are forced to grow too rapidly and form a tumour, the immature cells of which in their turn are lashed by the gonadotrophic hormone to reproduce. There are two constituents of this hormone—prolan A and B; probably the one is concerned in the development of cancer and the other in that of sarcoma.

It is gratifying to find in late issues of the *Journal* further evidence of the beneficial action of stilboestrol in malignant disease.—I am, etc.,

Wigan. J. THOMSON SHIRLAW.

Adder Bite

SIR,—In his medical memorandum on adder bite (Nov. 21, p. 608) Dr. Paul Szekely asks: "Is there any specific or satisfactory polyvalent serum against adder bite in Great Britain, and, if so, is the serum to be administered in every instance?"

The answer to the first question is, unfortunately, in the negative. A certain amount of the Pasteur Institute polyvalent (viper) anti-venom serum used to be imported annually, but this source has dried up since the fall of France. None has ever been made commercially in this country so far as I know, but it is to be hoped that the matter will be taken up, as it is something of a minor medical disgrace that the recognized scientific antidote should be unobtainable in a country which abounds with adders and in which a small number of persons are bitten annually. Deaths are fortunately few, but they could probably all be prevented if serum were obtainable and administered within the first few hours.

All young children who are bitten ought to receive an injection, as the great majority of these have a very alarming illness, and it is in this age group that the majority of the deaths occur. In debilitated and elderly persons, also, serum is advisable. In the teens and early adult life milder reactions are the rule, as in the case of Dr. Szekely's patient, aged 23. As this case was not admitted until 23 hours had elapsed after the bite, it was too late for serum administration had it been available.—I am, etc.,

Hereford CHAS. W. WALKER.

Hand and Finger Lesions

SIR,—Surg. Cmdr. J. B. Oldham's letter (Dec. 12, p. 706) brings to light a state of affairs that is no mere myth and one that is worthy of immediate publicity. There is no doubt that much unfortunate surgery is performed on traumatic afflictions of the hand and fingers, and in explanation the following suggestions may be advanced: (1) Inadequate undergraduate teaching; (2) lack of knowledge of special mechanics of the hand; (3) unsuitable instruments and surgical technique; (4) misapplied radical surgery; (5) ignorance of recent advances in reconstructive surgery of this region.

The practical solution of this problem lies in the centralization, where possible, of these cases to units which are equipped to deal with them. The collective experience of these units should be crystallized and published, and a real advance in this neglected sphere will have been made.

Viewing the subject from the reconstructive angle it is no exaggeration to state that over 80% of late reparative surgery is made necessary by inadequate or misdirected primary treatment. These cases fall into four main groups: (1) Acute infections: misplaced incisions causing superficial and deep scar contractures. (2) Lacerations: failure to procure primary healing and to realize indications for skin grafting. (3) Fractures: disregard of established orthopaedic principles. (4) Burns: (*a*) delay in primary healing; (*b*) scar contracture due to avoidable secondary infection and uncontrolled oedema; (*c*) deformities due to indifferent splintage.

It can thus be seen that at a time when effective man-power is of paramount importance this constitutes a wastage which should be minimized by every possible means.—I am, etc.,

St. Albans JOHN N. BARRON.

Prevention of Blindness

SIR,—In your issue of Sept. 10, 1938, you kindly afforded me a little space in which I reported having drawn the attention of representatives of local authorities to certain aspects of the administration of the Public Health Act, 1936, Section 176, and the Blind Persons Act, 1938. Shortly after the publication of my communication the catastrophe of war fell upon us. In spite of this, public opinion and, I am glad to say, administrative opinion have become insistent that greater activity should be shown in an attempt to initiate further facilities for research in ophthalmology (prevention of blindness). The trend of public opinion is substantiated by the recent foundation of two ophthalmological research units: one in Oxford University and another, jointly, at the Royal College of Surgeons and the Royal Eye Hospital.

In view of the fact that much thought is being devoted to great changes in the organization of medical work after the war, may I refer to my letter of Sept. 10, 1938, and especially the suggestion that such authorities upon whom falls or will fall the burden of administration of the Blind Persons Act should be asked to contribute 1% of their annual expenditure on blind welfare to a central ophthalmological research board, representative of the contributing authorities and the ophthalmic branch of the medical profession, which would finance approved research units.

It is probable that some of the developing Regional Hospital Councils will desire to establish their own ophthalmological research units in local universities, but some co-ordination effort will be highly desirable, and this could be secured by a central ophthalmological research board. Pending the establishment of such a central authority—from experience I am well aware of the possible delay—local authorities, voluntary agencies, and private individuals are asked to contribute generously in support of progressive efforts of those research units already established.—I am, etc.,

Leeds C. G. KAY SHARP.

Phosphorus Poisoning and Blood Urea

SIR,—Mr. A. J. Blaxland and Dr. G. P. C. Claridge (Dec. 5, p. 664), in reporting their case of death following wounding with an explosive bullet, seem to have overlooked one important fact which should surely have influenced their diagnosis. This is the height of the blood urea (453 mg. per 100 c.cm.) on the day before death. In cases of hepatic failure both experiment and observation have shown that failure to "de-aminize" the blood amino-acids causes the level of these to rise markedly with a corresponding fall in the level of the blood urea, which may be so extreme that it vanishes from the urine. Not only is the high blood urea in this case against the diagnosis of liver failure, but the finding of what must have been fairly severe lesions in the kidney tubules would indicate that some form of renal failure had occurred. Whether this was due to incompatible transfusion or other causes it would now be difficult to say. The sudden onset of the anuria is puzzling, but so is the finding of liver necrosis microscopically.

To sum up, I feel that although this case was presented as one of acute phosphorus poisoning, without far more extensive investigations than have been reported it could certainly not be supported.—I am, etc.,

Coulsdon, Surrey R. E. REWELL

Periodic Medical Examination

SIR,—In his most valuable letter (Dec. 12, p. 709) Dr. S. T. Beggs has drawn attention to the increasingly important part played in the maintenance of maximum health by periodic medical examination. In the Friends' Ambulance Unit applicants are submitted to a short medical examination, and those whose health is obviously defective are weeded out. Some time later a much fuller examination is made. This includes functional tests, miniature *x*-ray of the chest, and study of the physical type together with a full clinical examination, taking in all about an hour.

This overhaul has revealed a number of progressive conditions such as bronchiectasis, bad teeth, chronic nephritis, and signs of maldeveloped physique. These persons have been either referred for specialist treatment or advised corrective exercise and games. Morbid interest in illness does not appear to be induced by examination under these circumstances, but rather is relief of mind experienced when some imagined trouble such as high blood pressure, tendency to hernia, or weak heart is shown to be absent. National fitness continues to be a matter of first importance in war and post-war planning. For this reason a method that detects cryptic disease and latent ill-health holds in medical planning a prime place.—I am, etc.,

London, W.C.1. H. F. BARNARD.

J. F. Sadusk and B. G. Anderson (*Amer. J. med Sci.*, 1942, **203**, 397), who record an illustrative case, indicate the rarity of chancre of the gum by the fact that it accounts for only 0.46 to 1.4% of extragenital chancres, and that only 157 examples are on record, very few of which are in the American and English literature. The present case was that of a woman aged 19 who denied any sexual perversion, but her partner was found to have secondary syphilis

Obituary

DAN A. POWELL, M.D.

Wales has suffered a great loss by the untimely death on Dec. 21, 1942, of Dr. Dan Powell, principal medical officer of the Welsh National Memorial Association for the Prevention and Treatment of Tuberculosis. Born at Bedlinog (Glam.) in 1884, he was educated at Pengam School and pursued his medical studies at the University College of South Wales and Monmouthshire, Cardiff, and Charing Cross Hospital, London. He was a University Exhibitioner at the hospital and graduated M.B., B.S.Lond. with honours in medicine in 1909, proceeding to the M.D. in the following year. He had qualified as L.R.C.P., M.R.C.S. in 1908. After holding a number of resident posts, including house-physician, obstetric house-surgeon, and R.M.O., at Charing Cross Hospital, he was appointed as one of the first tuberculosis physicians of the association in 1912, serving the area of Anglesey and Caernarvonshire. In 1921 he was transferred to the post of medical superintendent of the North Wales Sanatorium, Denbigh. In 1926 he became deputy principal medical officer, and when the principal post fell vacant, by the retirement of Prof. Lyle Cummins in 1927, he succeeded to it. He had served, first as lieutenant and then as captain, throughout the war of 1914-18, spending three years on the Western Front.

Powell was a man whose clinical capacity impressed itself on all who made contact with him early in his career. His administrative ability soon became manifest when he joined the association, and was responsible for the rapid promotion which brought him to its head. Indeed the two qualities have seldom been better exemplified in one person. He was not merely an office man. Throughout his fifteen years as P.M.O. he kept in constant personal touch with the association's widespread institutions and institutes, and with their officers, young and old. He had the administrative acumen to seek expert guidance wherever it could be found, and the judgment and character to form his own conclusions and take full responsibility for them.

During his term of office the progress of clinical knowledge brought about many changes in method and institutional procedure. The bed accommodation grew from 1,400 to 1,820. There was a great expansion of the consulting staff and of the facilities for radiological and bacteriological diagnosis, light treatment, and the surgical treatment of pulmonary tuberculosis. He had devoted much attention to miniature radiography and had worked out a plan of mass radiography for Wales before the Ministry's national scheme was inaugurated. He was a patriotic Welshman and rightly appreciated the importance of appointing officers native to the land and speaking its language, but only in so far as this policy would enhance the efficiency of the association. To an increasing extent in recent years he was serving on central bodies; he was chairman of the Joint Tuberculosis Council, member of the Standing Advisory Committee on Tuberculosis, the M.R.C. Committee on Industrial Pulmonary Disease, and the Prophit Bequest Committee of the Royal College of Physicians. In the Principality he was a member of the Councils of the Prince of Wales Hospital, the National Library of Wales, and the Welsh National School of Medicine, which latter body he also served as an honorary lecturer in the department of tuberculosis. He was an active member of the South Wales and Monmouthshire Branch and the Cardiff Division of the B.M.A.; he was chairman of the Denbigh and Flint Division in 1923-4, and when the Association met at Cardiff in 1928 he acted as vice-president of the Section of Tuberculosis; Powell was also a past president of the Welsh Branch of the Society of Medical Officers of Health. He found time among his other activities to make valuable contributions to the literature of tuberculosis, and his reports were models of clarity, brevity, and style.

Powell was a staunch friend and a most entertaining companion. He had a nice wit which he did little to exploit publicly, so that it came as a surprise to those who heard him for the first time as an after-dinner speaker. His place will be hard to fill, and there are many in Wales who mourn his death for personal as well as public reasons. Their heartfelt sympathy goes out to Mrs. Powell, who so ably and tactfully supported him in his work.

H. MEREDITH RICHARDS, M.D.

Dr. H. M. Richards, formerly medical officer at the Ministry of Health, died in his 79th year on Dec. 25 at Oxford.

Harold Meredith Richards was educated at University College, London, and qualified M.R.C.S., L.R.C.P. in 1891. He took the M.D.Lond. in 1892, qualifying for the gold medal, and M.D. State Medicine (gold medal) in 1893. Dr. Richards was a Fellow of University College. After holding various hospital appointments he was M.O.H. and School M.O. for Croydon, and M.O.H. for Chesterfield and Dronfield. When the National Health Insurance Act was introduced he was appointed by Mr. Lloyd George in 1911 as deputy chairman of the Welsh Insurance Commissioners, returning to his native city of Cardiff. In 1920 he was appointed medical officer at the Ministry of Health, and towards the end of his service did much of the groundwork in connexion with the Local Government Act, 1929, and the transfer of Poor Law hospitals to county councils. Although at Mr. Neville Chamberlain's special wish Dr. Richards's term of service was extended beyond his 65th year, he was compelled by ill-health to resign in 1930. He was a member of several departmental committees and the author of several articles and reports on public health subjects. A man of wide culture, he was excessively shy and modest, and was regarded with deep respect by his colleagues in the Public Health Service.

WILLIAM MacLENNAN, M.B.

We regret to announce the death on Dec. 24 at the age of 77, of Dr. William MacLennan, honorary consulting physician, Western Infirmary, Glasgow.

William MacLennan received his medical education at Glasgow University, where he graduated M.B., C.M. with first-class honours and gained the Brunton Memorial Prize awarded to the most distinguished graduate in medicine of the year. He pursued postgraduate studies at London, Paris, Bonn, and Berlin, and among his various appointments was that of resident physician to the Western Infirmary, Glasgow, and house-surgeon to the Glasgow Hospital for Skin Diseases. Dr. MacLennan was also university assistant to the chair of materia medica and therapeutics at Glasgow University, and was lecturer in the same subject. He was appointed assistant physician to the Western Infirmary, but after undergoing an operation on the throat some 25 years ago he decided to give up teaching and resigned his position, being thereupon appointed honorary consulting physician. Dr. MacLennan continued in private consulting practice and for a time acted as external examiner in medicine for Aberdeen University. During the last war he was a major in the R.A.M.C. and had charge of medical units at Oakbank and Yorkhill Military Hospitals. He published several articles in the medical press, especially on gastric diseases. He was the author of a *Manual of Diseases of the Stomach for Practitioners and Students.* Dr. MacLennan was married and had one son and three daughters.

COL. THE HON. MURRAY MacLAREN, P.C., C.M.G., M.D.

We announce with regret the death at the age of 81 of Col. the Hon. Murray MacLaren, formerly Lieutenant-Governor of New Brunswick.

Murray MacLaren, the son of Dr. Laurence MacLaren, was educated at the universities of New Brunswick and of Edinburgh. He qualified M.B., C.M. in 1884, and took the M.R.C.S.Eng. in 1885. In 1888 he proceeded to the M.D.Ed. The LL.D was conferred upon him by three universities, and he was also a Fellow of the American College of Surgeons. In the last war Col. MacLaren was Officer Commanding No. 1 Canadian General Hospital, with the First Canadian Expeditionary Force; he was also Deputy Director of Medical Services, Canadian Contingents in London. He was senior consultant surgeon to St. John General Public Hospital, and in 1914 was elected President of the Canadian Medical Association. In addition to his professional life he pursued an active public career, being elected M.P. for St. John City and St. John and Albert Counties, New Brunswick, 1931-4. He was also Minister of Pensions and National Health for Canada 1930-4. His distinguished record of public service was recognized in 1935 by his appointment as Lieutenant-Governor of his native Province of New Brunswick. He was Commander, Military Order of Avis, Portugal, and received the honour of C.M.G. in 1916.

L. R. BRAITHWAITE, F.R.C.S.

W. A. writes:

Your excellent obituary notice of Mr. L. R. Braithwaite lacks one acknowledgment which I am sure he would have wished to make—namely, to his chief teacher and inspirer in the art of surgery, Mr. Edward Ward, senior surgeon and professor of surgery in his time, under whom he served as dresser and house-surgeon. No one acknowledged Mr. Ward's great influence as an example and a teacher more heartily than Lord Moynihan himself. And yet all these passing and personal traditions are only phases of the great and perennial tradition of the Leeds School of Surgery.

Dr. James E. Outhwaite writes:

As a former dresser to the late Lord Moynihan, I came in contact closely with Mr. L. R. Braithwaite, whose obituary you published last week. Every word is true and deserved. There is, however, one unfortunate error. The hospital which Mr. Braithwaite adorned, and which mourns his loss, is described variously as the Leeds General Infirmary and the Leeds Royal Infirmary. Both descriptions are wrong. It is the General Infirmary situate at Leeds. Our predecessors, both in the flesh and in the craft, who laid the foundations of this noble charity chose rather to serve humanity than one township, even though that was their own. Their choice should not be forgotten, least of all when one of the last men ever to have forgotten it was Leonard Ralph Braithwaite.

WILLIAM HENRY PAINE was born in 1859 at Usk, Monmouthshire, of humble parentage. He attended the local grammar school, and in 1874 was apprenticed to a chemist at Newport, which accounts for his claim in recent years to have had "66 years of physic." After three years at Newport, he went as dispenser assistant to Mr. Sayers of Lewisham, S.E., whose daughter he later married. From there he entered University College and Hospital as a medical student in 1880. Working as dispenser in the evenings, attending lectures and hospital practice in the daytime, and burning the midnight oil, he worked steadily through the course, qualifying M.R.C.S. in 1885. An assistantship at Highbury followed and the diploma of L.R.C.P. in 1886. Then, with a little borrowed capital, Dr. Paine married and set up his plate in the newly developing district on the boundary of Tottenham and Hornsey. Hard work and patient attention to clinical detail built him a local reputation, especially for midwifery (he attended 200 cases a year for several years), and a solid family practice extending to the third generation of patients. For a time he was parish medical officer in West Green. A long illness seriously set back his prospects in 1907-8, but with the same dogged determination he came back to build up the practice again for the sake of his young family. He continued within a stone's throw of his original house till 1934, often walking 10 to 15 miles on his daily round after the days of horses. He never learned to drive a car and disliked being driven. Throughout this long period he kept abreast of medical developments by assiduous reading and attending clinical meetings of the B.M.A. North Middlesex Division and the N.E. London Clinical Society, each of which he served as chairman and as president for a term. Dr. Paine was an active member of the Middlesex Panel Committee, and his pharmaceutical experience was invaluable when he was appointed to investigate excessive prescribing in pre-R.M.O. days. He took an active interest also in municipal politics, was president of the West Green Ratepayers' Association for 25 years and an urban councillor for 4 years. One thing that always impressed his colleagues was his gift of the right words to those whom no professional skill could cure. A gentle, lovable nature endeared him to a wide circle of friends and patients. Some of them would not let him retire, so that he was consulting as recently as 1940. But after 1937 his health began to fail, and the deaths of his elder daughter and wife in quick succession were shocks he could not sustain, and he passed peacefully away on Dec. 13, shortly before his 84th birthday, sincerely mourned by all who knew him. A married daughter and a son in practice in Northamptonshire survive him.

Universities and Colleges

UNIVERSITY OF OXFORD

In a Congregation held on Dec. 12 the following degrees were conferred:

D M.—R. H S. Thompson
B M—R. G White.

UNIVERSITY OF LONDON

The University has been informed that an "Ordinance to govern the Establishment, Incorporation, and Regulation of a University in Ceylon" has been passed by the State Council of Ceylon, and steps are being taken for the early inauguration of the Ceylon University.

The following have been recognized as teachers of the University in the subjects indicated in parentheses: *London Hospital Medical College:* Dr. C. Wilson (Medicine). *King's College Hospital Medical School:* Drs. W. G. Oakley and R. S. B. Pearson (Medicine).

The regulations for the Academic Postgraduate Diploma in Medical Radiology have been amended. Details of the alterations were published in the *University of London Gazette* dated Dec. 4, 1942 (p. 71).

The Sanderson-Wells Senior Prize has been awarded to A. J. Wells Beard, M.B., B.S. (St. Bartholomew's Hospital). The subjects for essays for the junior and senior prizes in 1943 are "The Role of Iron in the Nutrition of Man" and "Permanent Stigmata of Dietary Deficiencies during Infancy" respectively.

UNIVERSITY OF LIVERPOOL

The following candidates have been approved at the examinations indicated:

M D—H. F. Harwood.

M B., Ch B.—[1,3]S M. Green, [1,2]S E Keidan, [1,3]R C. Nairn. *Part III:* D. Annis, Margaret J Blackburn, H. O M. Bryant, Eva V. Cooper, K. H Dalrymple, A. S. Davidson, J G. K. Dean, J. N Dearnaley, P. J. Devlin, J F. Doherty, K. E A Donnellan, Ann Donnelly, H G. Frank, H Friend, F. D Griffiths, F. E D. Griffiths, Elizabeth M Harper, F. A. H. Inman, A Jolleys, D A. Kininmonth, E. D G Kirkwood, H Lewis, R. H. Martin, E Martinez-Alonso, A F Murphy, J S. Redfern, R L. B. Roberts, A. J. Robertson, P. L. Robinson, M. J. R Ryan, J M. G Sarson, Betty Schofield, H. R Shepherd, G. H. Thomas, Doreen M Watt; H. O Williams, Margaret Woolfenden. *Passed in Separate Subjects:* Mary A Allan, Beryl R Bentley, K W Boggis, W G Canning, G Davies, J J. Lieben, I. P Madhok, and Margaret L Magee (Medicine; Obstetrics, and Gynaecology) Muriel C Andrews, I. H Foy, Eirwen M. Jones, Jean C. Miller, K. H Oldfield, K. H. Slatter, and Nora Taggart (Medicine and Surgery). E R Banner, A. W. Merrick, and E Scott (Surgery, Obstetrics, and Gynaecology). *Part II:* [5]J. Ainsworth, A. M Brenner, [5]Constance M Davis, P S Deardon, Margaret P Diamond, E G Donovan, P M. Edis, [5]K. B. N. Freeman, J. Gould, N. J. Gourdji, A Griffith, J E. Hall, D. A. Harbord, [5]Betty Hargreaves, E. T. Harrison, Ethel J Higgitt, H Holden, Winifred L. Hollick, C. Hopkins, J G Jones, J. D. King, R. V. Kinnish, J. W. Langley, Constance G. Lee, V Leitner, Margaret J Lezama, A. McPherson, W. E S. Marshall, J W. Maybury, J. K. Meiring, Janet B. Mercer, E. W. Parry, Sheila L Richardson, J J Rivlin, [5]W Sircus, Margaret Slater, A. Stone, A. H Swithinbank, Barbara K Thompson, D W Townley, J G. Warbrick, Elspeth M Whittaker, Margaret A. Williams, [4,5]R. S. Williams, F. B. Wright. *Passed in Separate Subject:* Simone J van Son (Public Health)

[1] Second-class honours. [2] Distinction in Medicine [3] Distinction in Obstetrics and Gynaecology. [4] Distinction in Forensic Medicine and Toxicology [5] Distinction in Public Health.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW

Mr. R. Watson-Jones will deliver a lecture under the auspices of the Dr. John Burns Fund, entitled "Surgical and Rehabilitation Treatment of Bone and Joint Injuries," in the hall of the Faculty (242, St. Vincent Street, Glasgow) on Wednesday, Jan. 13, at 4 p.m.

The Services

The King has granted permission to Lieut.-Col. M. B. H. Ritchie, D.S.O., O.B.E., late R A.M.C., to wear the Order of George I, 4th Class, with Swords, conferred upon him by the King of the Hellenes in recognition of services in the cause of the Allies.

Col. (temp. Brig.) E. M. Cowell, C.B., C.B.E., D.S.O., T.D., has been appointed a Director of Medical Services, and has been granted the paid acting rank of major-general.

Flight Lieut. Thomas Henry Cullen, R.A.F.V.R., has been appointed M.B.E. (Military Division). The citation in the *London Gazette* of Dec. 29 reads as follows:

"A few days before the German invasion of Crete, this medical officer fell sick with dysentery at Maleme When the heavy air attack on Maleme began, although too weak to walk properly, he immediately attended to the wounded and continued to do so under fire until his post was captured Fl Lieut. Cullen then established a first-aid post in a near-by village and worked alone and without sleep for the next three days, when he was joined by two doctors of the New Zealand Forces. Over 1,000 wounded were passed through this medical post before it was finally taken over by an Australian field ambulance. Fl. Lieut. Cullen displayed devotion to duty and courage of the highest order."

Temp. Surg. Lieut. R. McF. Kirkpatrick, R.N.V.R., has been awarded the D.S.C. for great gallantry, leadership, and devotion to duty in the raid on Tobruk in Sept., 1942.

Surg. Lieut. A. L. Johnson, R.C.N.V.R., has been mentioned in dispatches for services in action with enemy submarines while serving in H.M. Canadian ships.

CASUALTIES IN THE MEDICAL SERVICES

Lieut. DAVID WALTON FELL, R.A.M.C., who died of wounds in North Africa in November, was the third son of Dr. and Mrs. A. N. Fell of Colchester. He was educated at the University of London, graduating M.B., B.S. in 1938, also taking the M.R.C.S., L.R.C.P. in the same year. He held posts at St. Mary's Hospital and St. Bernard's Hospital, Southall, before entering the R.A.M.C. in February of last year. He was a member of the B.M.A. He leaves a widow.

Wounded and Prisoner of War.—War Subs. Capt. A. C. P. D Thomson, R.A.M.C.

Missing.—Capt. C. W. Peck, R.A.M.C.

Prisoners of War.—War Subs. Capt. G. A. Anderson, R.A.M.C., Capt. M. G. Braham, R A.M.C., Major J. W. D. Bull, R.A.M.C., Lieut. R. G. Drummond, R.A.M.C., Major D. W. Gillies, R.A.M.C., Capt. J. B. Hannah, R.A.M.C., Capt. W. R. Jackson, R.A.M.C., Capt. E. R. S. Phillips, R.A.M.C., Capt. H. Silman, R.A.M.C., War Subs. Capt. B. J. Smith, R.A.M C., Lieut. J. C. T. Sykes, R.A.M.C

Medical Notes in Parliament

Call-up of Doctors and Protection of Practices

Sir E. GRAHAM-LITTLE inquired on Dec. 17 in how many instances the Minister of Health had overruled resolutions taken by the Central Medical War Committee on allocations of medical man-power. Mr. BROWN answered that in a comparatively few cases he had decided that recruitment of individual doctors for the Forces should be postponed for varying periods. With negligible exceptions the Committee had on reconsideration concurred in his view. No formal appeals were involved in this procedure. A doctor could apply for postponement of calling up on grounds of personal hardship or for registration as a conscientious objector in the same way as any other person.

Mr. Brown further stated that he had no power either to interpret or to enforce private arrangements made between practitioners for protection of the practices of their colleagues, although he had recommended insurance committees to assist in the operation of the scheme so far as it related to insurance practice. The right of a registered practitioner to join an insurance medical list could not be limited to participants in the Protection of Practices Scheme. The private scheme was enforceable by agreement between participating practitioners, and its general administration was undertaken by Local Medical War Committees. The scheme did not involve any infringement of the provision of the National Health Insurance Regulations as to free choice of doctor.

Medical Certificates.—Mr. ERNEST BROWN stated on Dec. 17 that insurance practitioners were required to give medical certificates only for the purposes of the National Health Insurance Acts. They were not forbidden to give and charge for certificates required for other purposes. Mr. HIGGS, who raised the matter, said that charges of 1s. or 2s. 6d. for each certificate of ill-health were made when these certificates were demanded by an employer.

Free Insulin.—Mr. ERNEST BROWN on Dec. 17 pointed out that a person insured under the National Health Insurance Acts was entitled to obtain insulin as part of his medical benefit if prescribed by the doctor attending him. Local education committees might provide insulin free or at reduced rates for children and young persons attending schools and educational institutions if the necessary sanction had been obtained. A general sanction was now being given. Local authorities had power, with the approval of the Minister of Health, to provide temporary supplies of insulin for poorer inhabitants of their districts. Mr. Brown said he was conveying his approval to the exercise of this power for the period of the war and issuing a circular drawing attention to it.

Treatment of V.D in the Army.—SIR JAMES GRIGG stated on Dec. 17 that all soldiers returning from leave were medically examined, and if found to be suffering from venereal disease were admitted to the venereal disease departments of certain military hospitals, none of which was designated as a venereal disease hospital.

Diphtheria.—Between Jan. 1, 1940, and June 30, 1942, approximately 5,000 cases of diphtheria were notified in England and Wales among immunized children under 15. The number of deaths from diphtheria among immunized children between Jan. 1, 1942, and June 30, 1942, was 17.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* decline in the notifications of infectious diseases has been general. The only exceptions were a rise of 14 for acute pneumonia and 21 for cerebrospinal fever.

The fall in the notifications of scarlet fever took place mainly in the South, though there were rises in London and Middlesex of 28 and 26 respectively; in the North the only notable difference in the trend was an increase of 27 in Lancashire.

The subsiding of the diphtheria outbreak in Middlesex, Edmonton M.B., where there was only 1 case compared with 111 in the preceding week, was the main factor in the decline of 71 for the whole country.

There were 166 fewer cases of whooping-cough than in the preceding week: the largest decreases were those of Lancashire 45, and Middlesex 25.

Although there were only 5 fewer cases of measles than in the preceding week there were large variations within the counties. Roughly, the South experienced an increase and the North a decline. The largest of the rises were Middlesex 177, Derbyshire 121, Essex 71, Nottinghamshire 64, Durham 60, and Wales 125. The counties returning the largest drops were Lancashire 365, Yorks West Riding 133, and Northumberland 58.

There were 14 more notifications of acute pneumonia than in the preceding week, but the only variation of any size within the counties was a rise of 34 in Warwickshire; 59 of the 81 cases recorded in this county were reported from Birmingham C.B.

The incidence of cerebrospinal fever, for which a relatively large increase of 21 cases was recorded, is now at a higher level than for the past six months. The largest totals during the week were Durham 10, Lancashire 16, and Yorks West Riding 9, accounting for 36% of the cases in the country; the remaining cases were scattered throughout 26 counties.

There were 20 fewer cases of dysentery than in the preceding week; the weekly total was the lowest since the beginning of September: 42% of the cases occurred in two counties—London 24 (an increase of 6 cases), and Lancashire 23 (a decrease of 11 cases); the remaining 66 were reported from 23 counties.

In *Scotland* the chief features of the returns were the fall of 70 cases in the incidence of scarlet fever, and the rise from 16 to 26 notifications of cerebrospinal fever. The downward trend for scarlet fever was fairly general throughout the country, while the rise in cerebrospinal fever was confined to the western area, where the total rose from 11 to 22. After an interval of twelve days another case of small-pox was reported on Dec. 30 in Edinburgh. The patient was the widow of a previous victim of small-pox. This was the 36th case since Nov. 1; of these, 8 patients have died and 12 remain in hospital.

In *Eire* 8 cases of poliomyelitis were reported during the week—a further drop. Typhus has reappeared in Co. Galway, where one case was reported from the rural district of Galway.

Quarterly Returns for England and Wales

The birth rate for the September quarter was 16.1 per 1,000. This was the highest rate recorded in this quarter since 1930 and 1.0 above the average of the third quarters of 1937-41. Stillbirths were 31 per 1,000 of the total births, this being the lowest figure since registration of stillbirths began. Infant mortality was 40 per 1,000 live births, 5 below the average of the ten preceding third quarters and equal to the low record of 1939. The general death rate was 9.3 per 1,000, and was 0.7 below the average of the five preceding third quarters. As a consequence of the lowered death rate and increased birth rate the natural increase (excess of births over deaths) was, at 71,362, considerably larger than in the immediately preceding third quarters. The chief feature of the notifications of infectious diseases during this quarter was the large number, 1,724, of cases of dysentery.

Quarterly Returns for Northern Ireland

The birth rate during the third quarter of 1942 was 24.1 per 1,000, 3.8 above the average rate for the third quarters of the five years 1937-41. The infant mortality was 65 per 1,000 registered births, 3 in excess of the average of the corresponding quarters of the five preceding years. The general death rate was 11.2 per 1,000, and was 0.3 below the five-year average. The death rate from all forms of tuberculosis was 95 per 100,000, compared with 86 for the average of the September quarters of the five preceding years. The increase was due to pulmonary tuberculosis, while other forms of tuberculosis declined; the deaths were 232 and 63, as compared with 206 and 71 for the five-years average.

Returns for the Week Ending December 26

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 2,054, whooping-cough 837, diphtheria 731, measles 10,888, acute pneumonia 671, cerebrospinal fever 64, dysentery 103, paratyphoid 3, typhoid 6.

No. 50

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Dec. 19.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1942					1941 (Corresponding Week)

Rate per 1,000 total births (including stillborn)								39		

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Includes paratyphoid A and B for Northern Ireland.

‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Medical News

We have much pleasure in recording an event which, to the best of our knowledge, is unique in the annals of the B.M.A.—namely, the completion by both a husband and wife of fifty years' membership of the Association. Dr. Andrew Maitland Ramsay of St. Andrews joined the B.M.A. in 1888 and his wife, Dr. Elizabeth Margaret Ramsay, in 1893.

A meeting of the Therapy Section of the Faculty of Radiologists will be held at 32, Welbeck Street, W., on Saturday, Jan. 16, at 10.15 a.m., when there will be a discussion on "The Treatment of Carcinoma of the Prostate," to be opened by Mr. E. W. Riches, Mr. I. G. Williams, and Dr. A. Haddow.

A series of talks under the heading "Reshaping Man's Heritage" will be broadcast on Fridays from 7.40 to 8 p.m., beginning Jan. 15 These talks form a counterpart to those broadcast during the autumn under the title of "Man's Place in Nature," and are intended primarily for discussion groups. The following is the full schedule as at present arranged: Jan. 15: Man's Heritage, by H. G. Wells; Jan. 22: Man's Food, by W. F. Crick and J. C. Drummond; Jan. 29: The Good Earth, by W. G. Ogg; Feb. 12: Fighting Man's Competitors, by J. W. Murro and James Fisher; Feb. 19: The Future of Food, by Sir Edward V. Appleton; Feb. 26: The Conquest of the Germ, by L. J. Witts; March 5: The Conquest of the Tropics, by H. W. Kauntze; March 12: The Banishment of Pain, by L. J. Witts; March 19: Preventive Medicine, by James M. Mackintosh; April 2: Reshaping Man's Heritage: Biology and Human Welfare; the Future, by Julian S. Huxley. The B.B.C. has also arranged a series of discussions on education under the title "Living and Learning," which will begin in the Home Service programme on Jan. 18 at 7.35 p.m. Among the issues to be discussed will be the education of young people between 14 and 20, the educational opportunities open to adults, the common school, and the place of religion in education. It is understood that medical men will take part in the discussion.

The Middlesex County Medical Society has formed a committee to initiate, encourage, and facilitate medical research. Seven big general hospitals (7,064 beds), two sanatoria (1,408 beds), one mental hospital (1,997 beds), as well as the tuberculosis and school medical officers and the central administrative staff, are represented on the committee. It is hoped to arrange teams to study especially the common and yet controversial problems of hospital medicine. The immense wealth of clinical material in the Middlesex County Service, and the excellent facilities of their pathological departments, should enable useful information to be collected.

Dr. Ronald Henry Tasker of the Burmah Oil Company is reported missing through enemy action at sea in November.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.) Orders for copies of the *Journal* and subscriptions should be sent to the Secretary.

TELEPHONE No.—B.M.A. and *B.M.J.*: EUSTON 2111.

TELEGRAPHIC ADDRESSES.—EDITOR, *Aitiology Westcent, London;* SECRETARY, *Medisecra Westcent, London.*

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

QUERIES AND ANSWERS

Income Tax

Employment of Wife

"PHI'S" family live in the upper part of their house, the lower part being devoted to the practice. A caretaker lives downstairs but is away two half-days each week and is not responsible for night calls. He pays his wife £1 a week for the following duties: (*a*) taking messages, etc., on two half-days a week, (*b*) taking night calls in his own absence, (*c*) advising urgent callers, etc., as to his probable whereabouts, and (*d*) engaging and supervising staff and their work in the rooms used professionally. Is he entitled to deduct the £1 a week as expenses of the practice?

⁂ "Phi" does not mention whether and to what extent his wife receives "pin-money"; if the £1 a week is additional to a normal allowance his claim will be strengthened. Apart from this the case seems a marginal one. Professional men generally receive some assistance from their wives—solicitors and accountants have some professional and 'phone calls at their private residences—and the point at which this sort of arrangement amounts to an employment of the wife in the practice is difficult to fix, and may well vary according to the views of the persons attempting to do so. In this case the inspector of taxes takes the view that the payment does not comply with the statutory requirement that it shall be made "wholly and exclusively . . . for the purposes of the profession." There is a chance that Commissioners might take a different view on an appeal being made, but we should not regard the chance as a good one.

Allowance for Wife

M. R. asks: "As a doctor's wife with a 168-hour week am I entitled to a rebate on income tax to the value of £80?"

⁂ A married man is entitled to a "personal allowance" of £140, as compared with the bachelor's allowance of £80. The section (Finance Act, 1920, Sec. 18, as subsequently amended) provides also that "if the total income of the claimant [i.e., the husband] includes any earned income of his wife, the deduction . . . shall be increased by an amount equal to nine-tenths of that earned income but not exceeding in any case eighty pounds." M. R. does not mention any "earned income" of her own against which the claim can be made. By way of illustration, however, we may point out that if her husband pays her a salary of £2 a week as fair remuneration for assistance in his professional work her liability for 1942-3 would be as follows:

Amount of remuneration		£104 0 0
Deduct—Earned income relief (1/10th)	£10 10 0	
Special allowance	£80 0 0	
		£90 10 0
		£13 10 0

Tax at 10s in the £ £6 15s

LETTERS, NOTES, ETC.

First Aid for Fractured Spine

Dr. N. PINES writes: The vital importance of correct handling of a fractured spine by first-aiders prompts me to send the following note. (1) *Diagnosis.* I usually recommend members of my class to ask the injured man, if he is conscious enough for that, to move his fingers or his toes, but not his limbs. The reason is simple: if there is no movement and no pain with this attempt at movement the spine is fractured; in fracture of any other part of the body movements and pain occur. (2) *Transportation.* The greatest danger is at the moment of turning the injured man into the desired position. Once he is already turned the possibility of further injury is lessened. That is why two years ago I constructed a special stretcher, a description and drawing of which you published on March 30, 1940 (p. 546). It consists in principle of an ordinary board, with cross-pieces, which can be folded up or fixed across at any height, thus allowing the stretcher to be fixed to the patient in the same position as that in which he is found. Only after that is the patient turned round and carried away When fixing the stretcher one can of course arrange for the patient to be carried in the prone or the supine position.

Diphtheria with Perforation of Larynx

Dr. R. W. STEPHENSON senior medical inspector, Sudan Medical Service, writes: A child aged about 2 years was admitted to hospital with a history of two days' fever. Careful examination failed to elicit any physical signs, and as the temperature was fluctuating between 99° and 102° F. it was presumed to be a case of malaria, though blood slides were negative. Treatment with quinine was instituted and the temperature settled. On the fourth day after admission the child developed a slight cough, and later the same day emphysema of the neck. Each time the child coughed the tissues of the neck became distended with air. There was little distress or difficulty in breathing. Examination of the throat failed to reveal any abnormality and no membrane could be seen. A swab was taken and was found to contain Klebs-Loeffler bacilli. Anti-diphtheritic serum was given in full doses and the patient made an uneventful recovery.

Corrigendum

In the article entitled "Work of the Medical Corps in the U.S.S.R.," published in the *Journal* of Dec. 19, 1942, p. 734, under the cross-heading "Non-medical Personnel," faulty translation rendered incorrectly "the Red Cross and Red Serpent organizations." The name should have been "the Red Cross and Crescent organizations."

ABDOMINAL WOUNDS IN WAR: TREATMENT OF INDIVIDUAL LESIONS*

BY

Sir JAMES WALTON, K.C.V.O., M.S., F.R.C.S.

Surgeon to the London Hospital

The wound of entry caused by a rifle bullet usually has a small more or less circular appearance. If inflicted at very short range, as in accidental or suicidal lesions, there may be much bruising and local trauma and a relatively large wound of exit. In such cases the blow of impact is very considerable and there is much shock. At an intermediate range there is less local trauma, but the patient is knocked out and brought to a complete stop at the time of wounding. Shock and collapse are still considerable, and are probably increased by internal haemorrhage. There is usually severe pain. At a long range the impact is much less, and it occasionally happens that in the excitement of the engagement the man may not even know that he has been injured. The velocity of the missile may be so diminished that there is no wound of exit, and in some cases it fails to enter the abdominal cavity but travels for a certain distance in the layers of the abdominal wall. In such cases the wound is relatively clean and sepsis is almost entirely dependent upon the presence of visceral injury. In the last two varieties any visceral wounds consist of small clean punctures which are more amenable to simple suture.

Lacerated and Bayonet Wounds

Injuries caused by fragments of H.E. shell are nearly always more disruptive, so that even a small fragment which makes a clean small wound of entry causes considerable laceration of the underlying muscle and irregular tears of the viscera. Such small fragments have a very high initial velocity, which, however, is soon lost against the resistance of the tissues, so that the fragment may not traverse the body but remains embedded within it. Larger masses having a much higher momentum will probably pass through the body and not only cause wide destruction of the viscera but form large jagged wounds of exit. All such fragments, being irregular, are much more prone to carry in pieces of clothing and sometimes even metallic and other bodies which have been present in the pockets. They are therefore, if not treated early, practically always followed by severe sepsis even if the gastro-intestinal tract is not injured.

Large lacerated wounds may occur from glancing blows by irregular missiles. Direct blows of this nature cause so much local injury and collapse that survival is as a rule short. Such lacerations may involve considerable destruction of the abdominal wall, either of all layers—in which case there is much prolapse with perhaps injury of the intestines—or of the cutaneous and muscular tissues only. In this and in past wars remarkable cases have been recorded of extensive prolapse of the intestines, in some of which the patient, supporting his intestines in his hand, has walked to aid and yet recovery has taken place. A satisfactory result will naturally depend upon the time at which treatment can be given. If seen at an aid post situated at a considerable distance from a hospital or mobile team, the intestines should be washed and replaced, the wound dusted with sulphanilamide, a few stitches inserted, and the patient sent on to hospital. If surgical attention can be given very soon, a dressing should be applied and operation undertaken at the earliest opportunity. Under general anaesthesia the intestines should be wrapped in a sterile towel wrung out in saline, and the wound cleaned in the usual way, with excision of all dead and severely lacerated tissues. The intestine is then carefully examined and, if uninjured, freely washed in saline and replaced. The peritoneum is sutured completely or closed so far as is possible. If the muscle has been much injured the cavity is dusted with sulphanilamide and the wound lightly packed with paraffin gauze. Antitetanic and anti-gas-gangrene sera should be administered. If recovery takes place there is of course considerable risk of subsequent obstruction from intestinal adhesions, and a large ventral hernia is almost certain to occur.

Bayonet wounds differ but little from stab wounds seen in civilian life, although, being incurred in the full fury of a charge and with all the strength of a powerful man, they are severe in character and have a very high mortality rate. Solid and hollow viscera are almost certain to be cut. There is severe shock and rapid collapse from the severity of the haemorrhage. If the patient is in a sufficiently good condition to stand operation this will be performed at the earliest opportunity and will follow the general lines, the chief attention being given to suture of the internal injuries and less to the cleansing of the superficial wound, which, being clean-cut, is less prone to become infected.

Crush Injuries

Severe crushes usually follow explosions of bombs and H.E. shells. They may be due to a direct blow from a mass of material hurled by the explosion, but more commonly occur, both in the field of battle and in injuries to civilians in air raids, when the patient is buried in masses of falling earth or masonry. In such cases the injuries are often widespread. There may be fractures of several limbs, crushes of the chest with fractures of ribs and injury to the lungs, or associated head lesions: with such a diversity of lesions and with the patient in a condition of severe shock an accurate diagnosis may be very difficult and sometimes impossible until a certain amount of recovery has taken place. In this type of lesion rupture of the solid viscera is more common and hence intra- or extra-peritoneal haemorrhage is more frequent than the escape of gastric or intestinal contents, but this may occur, as may rupture of a distended bladder. The symptoms of haemorrhage have been discussed in the first lecture, and it is on their presence and on the steady deterioration of the patient that the decision to operate will be made. Unless the patient is going downhill, as shown by an increase in the pulse rate, abdominal pain and distension, and a marked anaemia, it will often be better to delay operation for a short period. In some cases the haemorrhage will cease, the fullness, mild rigidity, and tenderness of the abdomen become more localized, and later a firm well-defined mass be formed as the blood becomes encapsulated. It may become so sharply defined that it simulates a large abdominal neoplasm. Such changes are more likely to occur with extraperitoneal haemorrhage around a kidney. The swelling will gradually decrease, taking perhaps 4 to 5 weeks to disappear, but in the end the patient may recover completely, although until the blood is absorbed there is always the risk of its becoming infected and forming a large abscess, which may have to be opened. If the haemorrhage is persisting, or if complete absence of abdominal movement on respiration, increase of pain, the presence of definite rigidity, or evidence of free gas in the peritoneum suggest a perforation of a hollow viscus, the abdomen will have to be opened. Access will as a rule be best obtained by a paramedian incision.

---

* The second of two lectures on abdominal surgery in war given at the British Postgraduate Medical School, Hammersmith, the first one covering the same ground as the article by Sir James Walton in the *British Medical Journal* of Feb. 21, 1942.

Haemorrhage

Whether the abdomen be opened as a step in the treatment of a perforating wound or on the diagnosis of internal haemorrhage with a crush, its presence will be evident from the amount of blood in the peritoneum. Its source must be located as rapidly as possible. With a penetrating wound the course of the missile will be known either by the presence of a wound of exit or by the radiological examination. With a crush the site of internal injury may be indicated by bruising of the abdominal wall. If absent, the most common sites—liver, spleen, kidney, and mesenteric vessels—must be examined in turn.

The liver is one of the commonest viscera to be injured. It occupies a relatively large area and is of a soft consistency, so that it is easily ruptured. Irregular tears may run from the free margin into the substance and bleed very freely. Much has been written on the assumed difficulty of suturing this organ owing to its softness, and many suggestions have been put forward of methods to facilitate the closure. The use of decalcified plates, the suturing in of omentum, or plugging with gauze have all been advocated. In my experience none of these complicated methods are ever necessary. The wound can always be closed by the use of sutures, and since the blood pressure is low bleeding is controlled. It is true there is a tendency for the sutures to cut out, but this can be overcome by the use of thick catgut as a suture material and the use of mattress sutures. When a wide tear is present a long needle loaded with No. 6 catgut should be passed from in front backwards through the whole thickness of the liver on one side of the laceration, across the gap, and up the other side from behind forwards. On this same side it is passed back again from in front backwards about an inch down from its point of emergence, crosses the gap again, and returns on the first side from behind forwards. A large mattress suture is thus passed with one complete loop on one side of the tear and with the two ends ready to be tied as the other loop on the other side. Before tying these ends a second piece of thick catgut is laid under the loop, across the tear, and under the two ends to be tied; these two ends are now steadily tied and, having a wide bite of the whole thickness of the liver, will not readily cut out. The mattress suture, however, approximates the posterior edges but leaves the anterior gaping. The two ends of the second piece of catgut which passes under both loops are now tied; this tightens up the mattress suture and approximates the anterior edges. I have never known this suture cut out or fail to control the haemorrhage. For a large tear several such sutures may be required.

Perforating wounds made by a bullet or piece of H.E. shell can be closed by simple sutures, but in the latter case care must be taken to see that the piece of metal is not lodged in the liver. If so, it can usually be felt with a probe and extracted with long forceps. At times it may be impossible to extract, but its retention is always apt to be followed by abscess formation. The suture of a simple tear and the control of haemorrhage are unlikely to be followed by any complication.

The other most common source of haemorrhage is a rupture of the spleen. In many cases this organ has been torn after quite slight accidents. Patients have tripped over an uneven surface and, falling on the left side of the abdomen, have suffered from a severe internal haemorrhage due to an injury of this nature. In some cases there has been a curious delay between the injury and the onset of the symptoms of haemorrhage. The explanation of this is believed to be that the spleen pulp ruptures and forms a large haematoma under the relatively tough capsule, which gives way only after some hours or days; free haemorrhage into the peritoneum then occurs. The site of the haemorrhage can usually be determined from the fact that the blood is seen to be passing down from the left upper quadrant, and the tear in the spleen can usually be felt. By hooking two fingers over the gland and round the pedicle it can usually be drawn forward and inspected; if fixed, as it frequently may be if the site of previous disease, the paramedian incision should be carried up to the xiphisternal notch and, if right-sided, the falciform ligament should be divided between ligatures. If access is still insufficient the surgeon should have no hesitation in cutting the left rectus across in an upper and outer direction; this T-shaped incision always gives a good view. No attempt should be made to suture the organ, as its substance is much too friable. Fortunately its loss is readily compensated and no ill effects follow its removal. Haemorrhage can be easily controlled by gripping the pedicle, dissecting the vein and artery free, and ligaturing them in turn. The vessels may sometimes divide before they reach the hilum, and thus several have to be tied. By ligaturing the vessels independently the risk of injuring or removing a portion of the tail of the pancreas is reduced to a minimum. After removal the pedicle and the bed of the spleen should always be carefully inspected to make sure that the haemorrhage is controlled and to ascertain that the left lobe of the diaphragm has not been lacerated or ruptured. If a tear be found in it, it should be closed with a few sutures. It is in this type of lesion that the insertion of one pint of sterile saline into the peritoneal cavity before its final closure will often be found beneficial, but it should only be used if the injury was a crush, and not with penetrating wounds.

The amount of haemorrhage with a ruptured kidney is very variable. If the cortex has alone been torn there may be only extensive retroperitoneal haemorrhage, causing pain and some rigidity and tenderness in the loin on one side of the abdomen. Sometimes there is no haematuria, the presence of which means that either the pelvis or one of the calices has been injured. In such a case it may be very extensive and may, indeed, cause the bladder to fill with clot and give rise to clot retention. The peritoneum over the front of the kidney may be torn or cut by a missile, in which case the blood will pass freely into the peritoneum and the loss may be much more extensive. In some of these cases the decision as to the need for operation may not be easy, but will be based upon the amount of bleeding, whether internal or external. Since there may be doubt as to the site of the haemorrhage and of the presence of other lesions, especially if there be a perforating wound, access is usually best obtained by an abdominal approach. If the bleeding is coming from a renal area and if there has been haematuria, the peritoneum over the kidney is divided on the outer side of the colon and the kidney itself turned forward. At times the wound may be sutured and the organ saved; at others a nephrectomy is necessary: generally speaking, the indications for nephrectomy are a tear or injury of the pelvis or main vessels. In such cases the artery, vein, and ureter should preferably be tied separately. If the cortex be alone injured it should be sutured with thick unchromicized catgut, which should be passed as simple sutures. Mattress sutures are not necessary, and should not be used as they may cause wide areas of necrosis.

Rarely with crushes and frequently with penetrating wounds a relatively large vessel in the mesentery or omentum may be injured and lead to severe haemorrhage into the peritoneum. If only partly divided the artery will continue to bleed freely and its ends will not retract, so that it will not usually be difficult to locate; when divided completely the ends may retract from view and, with the patient in a state of collapse and shock, bleeding may temporarily cease. The source of the haemorrhage may then be more easily overlooked, but the tear of the mesentery or omentum will be visible, and in all such lesions divided vessels should be looked for carefully and securely ligatured. With the division and ligature of vessels in the mesentery there is the risk that an adjacent loop of gut has been deprived of its essential blood supply. It must be carefully examined, and if its condition is dubious it must be excised, the resected area passing well beyond the doubtful segment. In cases of doubt a small cut may be made in the doubtful area, free bleeding indicating that the blood supply is satisfactory.

Perforation

Perforations of the hollow viscera may be of all sizes and shapes, and are often multiple: in crush injuries several loops may be caught in the compressing force and cut completely across or show bursting wounds. With penetrating wounds a bullet or piece of H.E. shell may pass through several coils of gut or through the stomach. With a rifle bullet fired from a distance the wounds are more commonly small round punctures through which the mucosa has prolapsed. If inflicted at close quarters or by a ragged piece of H.E. shell there are more commonly large irregular lacerations, and in some cases several inches of the gut may be absent or represented only by a narrow strip of the muscular coat. The amount of shock in these cases is considerable, but only a short time must be allocated to overcoming it; for the results of treatment for all perforations are, as is the case with a perforated ulcer, dependent upon the time at which operation is undertaken after infliction of the injury. For this reason the mortality among patients who have to be transported for a considerable distance is extremely high. When a penetrating wound is present the abdomen will be opened during the necessary exploration of the abdominal wound. Perforations or rupture following a crush injury are not as a rule difficult to diagnose. The pain is severe, respiratory movements of the abdomen are absent, and almost without exception there is a degree of abdominal rigidity far in excess of that which would be caused by a tender and bruised muscle. In some cases there is evidence of free gas in the peritoneum. Here, as in all cases in which there is no penetrating wound, access is best obtained by a paramedian incision. When the peritoneum is opened there will usually be an escape of free gas and a considerable quantity of fluid. In the majority, however, this does not contain visible gastric or intestinal contents. The muscular wall of the gut is so paralysed by the injury that only enough escapes to cause severe irritation and infection of the peritoneum. The fluid is of a slightly mucoid type containing flakes of lymph, which in the later stages rapidly becomes purulent. It is in these cases more than all others that a rapid comprehensive survey is so essential; for not only are the perforations so frequently multiple but there may be additional damage to the solid viscera or other structures. Care must always be taken to examine for the presence of retroperitoneal lesions, which are especially common with the duodenum.

A wound of the stomach will generally be in the neighbourhood of the greater curvature, and may consist of a round or irregular perforation passing through both walls; it is very necessary, if a wound be seen on the anterior surface, that the posterior wall be carefully examined. In other cases a notch may be cut out of the greater curvature. The area posterior to the stomach must also be examined, for the pancreas or other structures may also be injured. The gastric wounds can generally be easily sutured by two layers of continuous chromic gut, the first passing through all coats, and the second, acting as an embedding suture, passing through sero-muscular coats only.

Wounds of the small intestine may be small perforations through both walls, cuts through the mesenteric or antimesenteric borders, or larger and more destructive lacerations. If multiple they may be close together so that there are several wounds in a foot or less of the gut, or they may be more widely separated. Generally speaking, better results follow the suture of several perforations than a resection; therefore, whenever it is possible to close the opening and to leave viable gut with an unnarrowed lumen, this method should be chosen. In order not to narrow the lumen the opening should of course always be sutured transversely to the long axis of the gut. When a portion of the intestine has been severely lacerated, when the mesentery has been severed or so injured that the blood supply has been destroyed, or in some cases where there are multiple wounds in a small area, resection may be necessary. After removing the injured segment widely enough to traverse normal tissue the surgeon may restore continuity by end-to-end suture or by closure of the ends and the performance of a lateral anastomosis. My own preference is always for end-to-end suture, as it can be rapidly performed and leaves no blind ends which might give subsequent trouble.

Injuries of the large gut are of the same general types as those of the small intestine, but the faecal contamination is more likely to be followed by serious infection of the peritoneum and wound. The wall of the large intestine is very thin, and, indeed, one is often struck with wonder, during an operation upon the colon, that an action of the bowels ever takes place; yet this thin-walled viscus is capable of the most powerful contractions. The highly infected contents, which may be solid or semisolid instead of fluid, the powerful muscular contractions, and the thin walls make an aseptic union much less certain than with injuries of the stomach or small intestine. For this reason many surgeons view an excision of a portion of the colon and end-to-end suture with trepidation.

Small wounds should be sutured, and the suture line may be reinforced by the application of near-by appendices epiploicae or a piece of omentum; but larger lacerations are often best treated by trimming up the edges and bringing the injured loop or the separate ends to the surface in the form of a temporary colostomy. Wounds of the lower pelvic colon or rectum should always be sutured, if possible, and an iliac colostomy usually performed above them. In most wounds of the colon the risk of infection is so increased that drainage with a rubber tube should be provided. If there has been a wound of entry or exit through the pelvis this must also be treated on general principles.

The fundus of the bladder may be wounded by penetration of bullets or pieces of H.E. shell if the viscus be distended, and when in a similar state it may be ruptured by a crush injury. Penetrating wounds through the pelvis may also injure the base of the bladder. With these injuries the presence of urine may be recognized in the peritoneum, or the nature of the lesion may have been diagnosed by the presence of haematuria or the inability of the patient to pass urine. Whenever possible wounds of the bladder should be sutured with catgut, but often it will be safer to drain the viscus with a suprapubic tube.

Abdomino-thoracic wounds present a serious problem. The treatment of these dangerous lesions has been admirably described in the comprehensive appendix on chest casualties by Mr. Tudor Edwards in the Emergency Medical Services instructions. He points out that it is essential to operate as soon as the patient is fit enough. These and all other war injuries of the abdomen are also fully discussed in the fascinating monograph *The Abdominal Injuries of Warfare*, by Gordon-Taylor.

If the missile has traversed the lower chest and the *x*-ray plate shows the piece of metal to be lying just below the diaphragm, so that it is certain that the lesions do not extend below the upper abdomen, it is best to deal with the injuries within the thorax as the first step, and then, by excising the wound in the diaphragm and perhaps enlarging it, to repair the visceral lesions within the abdomen, after which the diaphragm is carefully sutured. In many cases, however, the abdominal injury cannot be sufficiently explored by this method, so that after repair of the thoracic injury and the wound of the diaphragm a separate abdominal incision should be made. This is particularly true if the missile has passed downwards into the abdomen.

In some cases the thoracic wound may be of but slight importance but there is evidence of severe abdominal injury; the abdomen should then be opened as a primary measure. In yet others the wound may be at the level of the lower ribs in front, and access may be most readily obtained to both the abdominal and the thoracic cavities by cutting through the costal arch and, if necessary, the diaphragm.

This discussion has of necessity been brief, and I can only hope that I have given you a lead as to the methods you will find most useful. With a rush of casualties you will have to make quick decisions. Like all of us, you will make mistakes, but these will be reduced to a minimum by those who make one orderly investigation, arrive at a certain decision, and act rapidly upon it. Uncertainty and indecision are fatal errors.

L. H. Klinger and S. A. Blauner (*Amer. J. Dis. Child.*, 1942, 64, 462) record the occurrence of amaurotic family idiocy in identical twin girls. They have been unable to find a similar example in the literature.

CALORIE CONTROL

A NEW DIETETIC TREATMENT OF DIABETES MELLITUS

BY

A. C. CROOKE, M.D.

AND

ELLA SCOTT, S.R.N., S.C.M.

(From the Diabetic Departments of the London Hospital and Oldchurch Hospital, Romford)

Before the discovery of insulin the treatment of diabetes mellitus was essentially dietetic. It consisted in a severe restriction of the total calorie value of the food, with a relatively high proportion of protein and fat and a low proportion of carbohydrate. Subsequently a change in the diet of the diabetic patient requiring insulin was effected very slowly; indeed, 10 years after the discovery of insulin many patients were still being given diets similar to those of the pre-insulin period. In the last 10 years or so they have generally been allowed to increase the total calorie intake and the proportion of carbohydrate to protein and fat. It has long been our custom to give patients who are not excessively obese a diet which corresponds as nearly as possible to that which each individual might be expected to take if he had not got diabetes mellitus. The patient is encouraged to say if the diet is adequate or not, and adjustments are made accordingly. The total intake of carbohydrate, protein, and fat is controlled so that it does not vary from day to day, and the amount of insulin required to balance the patient is then determined by trial.

The dietetic restrictions necessitated by war have demanded a reconsideration of the problem of diabetic diets. The Government has allowed diabetic patients extra protein and fat but less sugar, yet it has not been possible for them to continue with their pre-war diets. In June, 1941, we began to try a new diet system which aimed at keeping the total calorie value of the food constant from day to day while allowing complete freedom of choice of food. Thus the patient can take a protein-and-fat breakfast of bacon one day and a carbohydrate breakfast of cereal the next. The new diet has proved to be very much easier for the diabetic to use, because the system eliminates the necessity for dividing different foods into carbohydrate, protein, and fat varieties, and because a much wider choice is available for each meal.

The Diet

TABLE I.—*Sample Diet of 2,000 Calories*

	Calories
Breakfast (450 calories).	
Tea or coffee, with milk ¼ pint	50
Oats or cornflakes, 1 oz.	100
Bacon, 1 oz, or 1 egg plus ½ oz margarine or butter	150
Bread, 1½ oz.	100
Butter, ¼ oz	50
....	
Mid-morning.—Tea or coffee, with milk ¼ pint, and 1 biscuit (¼ oz)	75
Dinner (500 calories):	
Lean meat, cheese, or fish to the value of	150
Fat meat or butter, ¼ oz.	50
Cabbage, cauliflower, sprouts, leeks, marrow, onions, lettuce, tomatoes, or radishes as desired	—
Potatoes, 4 oz.	100
Bread, ¾ oz, or vegetables to the value of	50
Rice, tapioca, or sago, ½ oz., or fruit to the value of	50
Milk, ½ pint	100
....	
Tea (425 calories):	
Milk, ¼ pint in tea	50
Bread, 3 oz.	200
Butter or margarine, ¼ oz	50
Jam, 1 oz	75
2 plain biscuits (½ oz)	50
....	
Supper (550 calories):	
Fish, cheese, or meat to the value of	150
Potatoes, 4 oz.	100
Vegetables as at dinner	—
Bread, 2¼ oz.	150
Butter, ¼ oz.	50
Fruit to the value of	50
Milk, ¼ pint in tea or coffee	50
....	

You can take the whole of your dinner in the form of sandwiches: bread 3 oz, butter ¼ oz., meat or cheese to the value of 150 calories; milk, ½ pint. In a temporary emergency you can take each of your four meals in the form of bread—five 1-oz. slices, and butter or margarine ½ oz.

If you are unwell and cannot eat your usual diet continue to take your habitual dose of insulin at the usual time and, in place of each of your four meals, take 20 lumps of sugar in tea or water.

The principle of the diet is to arrange each meal on the basis of a given number of units of food each equivalent to 50 calories. The patient is given a sample diet of 2,000 calories, which is typed on a sheet of foolscap paper (Table I). The diet can be readily increased by adding other units on the dotted lines provided for this purpose beneath each meal, or reduced by striking out unwanted units. On the reverse side of this diet sheet is typed a large variety of alternative foods in alphabetical order (Table II). Against each food is given the amount, in ounces, which yields approximately 50 calories. These figures are based on the food values given by McCance and Widdowson (1940).

TABLE II.—*The Following Quantities of Food each yield 50 Calories*

	oz.
Apples, English eating, with skin and core	4½
„ cooking, raw	4½
„ stewed without sugar	8½
Apricots, dried, stewed without sugar	2½
„ fresh	5½
Arrowroot	½
Bananas, without skin	2
Beans, baked	1½
„ broad, cooked	4
„ butter, boiled	1½
Beetroot, boiled	3½
Biscuits	½
Blackberries, raw	5½
Bournvita	½
Bread	¾
Carrots, boiled	8½
„ raw	7
Cherries, cooking, raw, with stones	4
„ eating, with stones	4
Cocoa	½
Cornflour	½
Cranberries	10
Currants, black, raw	5½
„ red, raw	7
„ dried	¾
Custard powder	½
Dates, without stones	¾
Figs, dried, raw	¾
Flour	½
Golden syrup	½
Gooseberries, dessert	4½
Grapes, black	3
„ white	2½
Honey	½
Horlick's	½
Jam	¾
Kellogg's cornflakes, All-Bran	½
Leeks, boiled	7
Lentils, raw	½
Loganberries, raw	10
Macaroni	½
Marmalade	¾
Melon, yellow, with skin	12½
Milk (¼ pint)	2½
Oatmeal	½
Oats, Quaker	½
Onions, boiled	12½
„ spring, raw	4½
Orange juice	4
Oranges, without peel or pips	4½
Ovaltine	½
Parsnips, boiled	3
Peaches, dried, raw	½
„ fresh	4½
Pears, cooking, stewed without sugar	6½
„ eating	4½
Peas, dried, boiled	1¾
„ fresh, boiled	3½
Pineapple, fresh	3½
Plums, eating, with stones	4½
„ cooking, raw, with stones	7
Potatoes, boiled	2
„ chip	¾
Prunes, stewed without sugar	2½
Raisins	¾
Raspberries, stewed without sugar	10
Raspberries, raw	6½
Rice	½
Sago	½
Strawberries, raw	6½
Sugar	2 lumps
Sultanas	¾
Swedes, boiled	10
Tapioca	½
Tomatoes	12½
Cheese	
Cheddar	½
Dutch	½
Gorgonzola	½
St. Ivel	½
Fats	
Butter	¼
Clotted cream	¼
Cream	½
Margarine	¼
Meat fat	¼
Fish	
Bloater, with bone and skin	1
Cod, steamed	2½
Eel, stewed, with bone	1
Haddock, smoked and fresh	1½
Hake	1½
Kipper, with bone and skin	1½
Lemon sole, steamed	2
Mackerel, fried	1
Plaice, steamed	2
Salmon, fresh	1
„ tinned	1½
Sardines	¾
Skate, fried	¾
Sole, steamed	2
Whiting	2
Meat	
Beef, sirloin, lean, roast	¾
„ steak, stewed	¾
Chicken	1
Corned beef	¾
Duck	½
Goose	½
Ham, boiled, lean	¾
Kidney, sheep, raw	1½
Liver, fried	¾
Mutton chop, lean, raw, with bone and fat	2½
„ leg, roast	¾
„ scrag neck, stewed	½
Pork, leg, roast	½
Rabbit, stewed	1
Tongue	¾
Tripe, stewed	2
Turkey	1
Veal, fillet, roast	¾

Egg 50 calories

Bacon 1 oz fried—150 calories

Unlimited amounts of the following: Asparagus, brussels sprouts, cabbage, cauliflower, celery, cucumber, endive, French beans, globe artichoke, gooseberries (stewed without sugar), lettuce, lemon juice, mushroom (stewed), mustard and cress, rhubarb (stewed without sugar), spinach, turnip tops, watercress

Results of Treatment

We have examined the records of all cases which have attended the diabetic departments of the London Hospital and Oldchurch Hospital since September 1, 1941. We chose this date because it was the day on which we first began to treat large numbers of cases with the new diet. Altogether 766 patients have attended, and 528 of these are using the calorie control diet. The cases have been subdivided into groups, which will be referred to as severe, mild, and old. All cases requiring 60 or more units of insulin daily have been classed as severe. Cases under 60 years of age requiring less than 60 units of insulin a day have been classed as mild. Cases aged 60 years or more requiring less than 60 units of insulin a day have been classed as old. The group of 528 cases using the calorie control diet have thus been subdivided as follows:

(A) Cases requiring insulin		477
Severe	107	
Mild	239	
Old	131	
(B) Cases not requiring insulin (all ages)		51

The general health of the patients in all groups has been as good on the new diet as on the old. There has been no increase in the frequency of insulin reactions or of diabetic coma; indeed, some of the most unstable cases have been more stable on the new diet. The difference in efficiency which exists between the calorie control diet and the old one is slight, and an accurate estimate of it can only be made by comparing the condition of each patient before and after starting the new diet. We decided, therefore, to take for this comparison only those cases requiring insulin which had attended the clinics regularly for a period of three months before and three months after first receiving the new diet. This excluded a large number of fresh cases which started using the new diet at the beginning of their treatment, many old cases which had not been seen for a long time owing to evacuation or other causes and which started the new diet immediately they returned, and some patients who did not attend regularly. Altogether only 192 out of 477 cases requiring insulin were suitable for further analysis. In this group a comparison was made between the body weight, insulin requirement, and amount of glycosuria during the three months before and the three months after starting the new diet. The results have been recorded as increased, unchanged, or decreased—representing the change that has occurred since the diet was altered. They are shown in Table III, in which the figures represent the number of cases in each group.

TABLE III

	Cases		Weight	Insulin	Glycosuria
Severe ..	47	Increased	20	24	7
		Unchanged	19	10	27
		Decreased	8	13	13
Mild ..	92	Increased	46	36	7
		Unchanged	37	29	58
		Decreased	9	27	27
Old ..	53	Increased	20	25	8
		Unchanged	20	22	32
		Decreased	13	6	13
Total ..	192	Increased	86	85	22
		Unchanged	76	61	117
		Decreased	30	46	53

The figures show a significant increase in the body weight in all groups. The number of cases requiring more insulin is nearly double the number of those requiring less, but there is a significant decrease in the amount of glycosuria in all groups. The changes in body weight and in the amount of glycosuria are therefore satisfactory, but the increase in the amount of insulin required might appear at first to be an unsatisfactory feature. Actually this is not so, because there is a natural tendency for diabetic patients to need more insulin in the course of time. We investigated the alteration in insulin requirements during a similar period of six months in a group of 100 unselected cases which were having the old type of diet throughout this period. In 39 cases the insulin requirement had increased, in 34 it was unchanged, and in 27 it had decreased. These figures may be compared with the figures in Table III. In the whole group of 192 cases the insulin requirement had increased in 44%, was unchanged in 32%, and had decreased in 24%. Another explanation of the increased insulin requirement is to be found in the greater total calorie value of the new diet compared with the old one. We analysed the calorie value of the diets in all the 192 cases requiring insulin and recorded it as increased when the new diet was more than 50 calories in excess of the old one, unchanged when it was within 50 calories of the old one, and decreased when it was less than the old one by more than 50 calories. We found that the diet had been increased in 98, was unchanged in 58, and had been decreased in 36 cases. We then compared the number of cases in each group with the change in insulin requirement; the results are shown in Table IV, the figures representing the number of cases in each group.

TABLE IV

	Insulin		
	Increased	Unchanged	Decreased
Diet increased ..	49	30	19
„ unchanged ..	21	18	19
„ decreased ..	15	13	8

In the group in which the calorie value of the diet had been raised the insulin requirement had increased markedly, but in the other two groups it had increased only slightly. This increase is less than would be anticipated from a comparison with the above-mentioned 100 cases, whose insulin requirement was observed for a period of six months while they were on the old diet.

Discussion

There is no adequate explanation of the effectiveness of the calorie control diet that can be based on our present knowledge of the physiological action of insulin. It is often assumed that when the carbohydrate value of a diet is increased the insulin requirement will also be increased. The idea conforms with the old conception that a fixed amount of insulin is necessary to utilize a fixed amount of carbohydrate. Actually when the carbohydrate value of a diet is raised the insulin requirement generally falls, provided the total calorie value of the diet is not altered. This effect was shown in a remarkable way by Prof. Ellis at the London Hospital in 1934. He found that severe cases of diabetes mellitus receiving daily 600 g. of glucose alone developed a marked temporary improvement in carbohydrate tolerance, necessitating the use of smaller doses of insulin. In the most notable instance in his series the reduction of insulin was from 192 units daily before the administration of glucose to 9 units daily on the twenty-first day after this treatment was begun. This interesting observation has received scant attention; but it forms a rational basis for the present treatment of diabetic coma with 4-hourly glucose and insulin, and offers an explanation of the effectiveness of our calorie control diet. It explains why the insulin requirement is actually less than anticipated in those cases in which the calorie value of the new diet is the same as that of the old one. It even suggests that patients might become reactionary as a result of taking the extra carbohydrate which is made available to them, but there has been no increase in the number of reactions reported by our cases.

The rate of change in the carbohydrate tolerance which occurs when carbohydrate foods are interchanged with protein and fat foods of the same calorie value by patients using the new diet is not rapid enough to cause instability, but in order to test the extent of permissible variation in the proportion of carbohydrate to protein and fat in the daily diet an experiment was undertaken at Oldchurch Hospital. Eight cases were chosen, including three of the most unstable diabetic patients attending either hospital. Each case was treated as an in-patient and was given a diet in which the proportion of carbohydrate, protein, and fat was kept constant at a normal level. The patients were made as stable as possible with insulin. The diet was then changed to an almost completely carbohydrate one of the same calorie value for two days. After this for another two days it was altered to one of the same calorie value consisting mainly of protein and fat. The carbohydrate diet was then repeated for two more days and the protein and fat one for a further two days. After this the patients returned to their normal diet. The blood sugar was estimated every two hours for 12 hours at the beginning of the experiment while the patient was on a normal diet. This was repeated on the second day after each subsequent change of diet, ending on the second day after returning to normal diet again. The six blood-sugar curves thus obtained were compared, and it was found that the range of values was of the same order in each case. The variation in the proportion of carbohydrate, protein, and fat in these diets was far greater than is ever likely to occur under normal circumstances. The experiment confirmed our belief that the unlimited interchange of these different foods which is allowed by the new diet is permissible even for the most unstable diabetic patients.

The calorie control diet has proved to be as satisfactory in every way as the older type of diet in use in these clinics. It is more simple to use, and it allows patients to replace foods that are scarce with foods that are plentiful. This has also meant that the diet is cheaper, since the carbohydrate foods in general are cheaper than the protein and fat foods which they have replaced. Finally, a group of patients, including some severe cases, have agreed to forgo the extra rations allowed to them by the Government, and they have remained just as stable and well without them. We believe, therefore, that even if the food rations have to be still further reduced and the diet of diabetic patients is affected they could be maintained in good health on the new diet.

Summary

A diabetic diet is described in which the total calorie value is kept constant but an unlimited variation in the proportion of carbohydrate, protein, and fat is permitted.

The effect of this diet has been examined after one year's trial on a large series of cases and found to be satisfactory.

THE ACTION OF RADIANT-HEAT CRADLES

BY
G. MALCOLM BROWN, M.D., Ph.D.

AND
K. MENDELSSOHN, M.A., Ph.D.[*]
(*From the Nuffield Department of Clinical Medicine, Oxford*)

The Physical Action of Cradles

The cradles used were those issued by the Ministry of Home Security, consisting of a sheet of polished metal bent in the shape of a horseshoe, and fitted with 12 carbon filament bulbs of 230 volts and 16 c.p. (about 65 watts) controlled by two switches. Each switch controls 6 bulbs and is so arranged that 2, 4, or 6 bulbs can be switched on. The object of the cradle is to supply heat to patients, and our primary aim was to investigate how this end was achieved by this type of cradle. It was also hoped that an analysis of the factors involved might suggest improvements in the apparatus.

The usual method of employing such cradles is to place the patient inside, covered with a blanket, and to drape another blanket over the whole cradle so as to retain the heat. The radiation emitted by the bulbs consists almost exclusively of infra-red rays of long wave-length, the remaining small percentage being emitted as visible light and short-wave infra-red rays. This radiation either falls directly on the blanket-covered patient or is reflected without change of constitution from the polished surface of the metal background. A certain amount is absorbed by the background, and the latter is gradually raised in temperature until it forms a source of long-wave infra-red radiation on its own.

Before reaching the patient, however, the radiation encounters the blanket, which becomes warmed on its upper surface and radiates heat as long infra-red rays on its own account. A certain amount passes through the blanket to the patient; but since the blanket is a good insulator, this is a very inefficient method of transferring heat. The energy which reaches the patient is thus much reduced in amount, but has been converted by the action of the blanket into very long infra-red rays. Some such convertor mechanism appears to be necessary; for, as we shall see, when a patient is placed in the unshielded cradle without the protection of a blanket he soon begins to suffer from burns. A mode of conversion was therefore adopted which involved a negligible loss of energy.

The metal background of the cradle was blackened[†] and the bulbs were covered with strips of thin metal which cut off the direct radiation completely, but which rapidly became hot and acted as a source of long infra-red radiation like the cradle background (Fig. 1). The blackening of the background ensured 100% absorption of the direct radiation incident upon it from the bulbs, so that in this "shielded" cradle the heat transmitted to the patient is furnished only by the thermal radiation of the cradle background and the shielding strips.

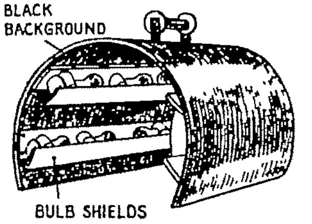

FIG. 1.—Modified cradle.

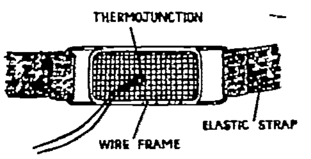

FIG. 2.—Skin thermometer.

In order to measure the radiation a small blackened square of copper was used, the temperature of which was measured by means of a thermo-junction fixed to its back. As this is heated by the incident radiation, which it absorbs completely, the radiation emitted from its surface is also increased, until after a few seconds the receiver is in equilibrium with its surroundings and emits as much as it absorbs. The temperature of the receiver is then the same as the effective temperature of the radiation field, provided that no heat conduction takes place.

For the physiological part of the investigation a suitable skin-temperature thermometer had to be devised. The form adopted (Fig. 2) consisted of a small grid about 4 cm. by 2 cm. of fine copper mesh carrying a thermo-junction on the side in contact with the skin, the whole being protected by a thin coat of shellac varnish The junction thus gave a mean value of the skin temperature over the whole area covered by the mesh because of the good heat conductivity of the latter. The skin was exposed to the air and was free to sweat, while the area obstructed by the wires of the mesh was sufficiently small not to interfere with the full access of the radiation to the skin. Three such instruments, of mesh sizes from 1 mm. to 2 mm., were found to give consistent readings over a wide range of radiation temperatures and air temperatures.

Experiments were carried out with a blanket over the cradle and all 12 bulbs switched on. The radiation meter was placed a few centimetres above bed level in the centre of the area covered by the cradle. Fig. 3 shows graphs of the observed temperatures of the receiver plotted against time. The receiver is affected by radiation from the bulbs and from the metal background, as well as by conduction through the air. The room temperature is represented by OA and the cradle is switched on at A. In the unshielded cradle the curve ABC is followed. At C the bulbs are switched off and the temperature immediately falls to F and dies away along FG as the cradle begins to cool.

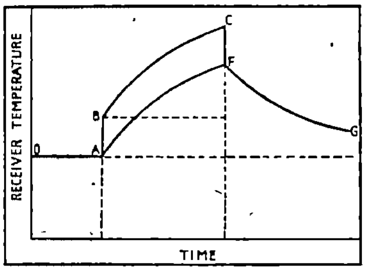

FIG. 3.—Radiation from shielded and unshielded cradle. For details see text.

In the shielded cradle, in which direct radiation from the bulbs is absent, the curve AFG is followed. Thus the contribution AB must be due to the direct radiation from the bulbs. This component of the radiation remains constant in time, as is evident from the fact that when the bulbs are switched off at C the drop in radiation recorded, CF, equals the initial rise, AB. The curves AF and BC are almost identical,[‡] and this implies that the amount of heat supplied by the bulbs to the cradle background is the same whether the bulbs are shielded or not. This is also corroborated by the fact that a few minutes after the bulbs have been switched off the radiation recorded in the shielded and that in the unshielded cradle are identical. This means that the direct radiation from the bulbs plays only a very small part in the total energy supply to the patient. The radiation from the background, however, which is represented by AF, increases steadily. Thus we have been able to separate the two components of the radiation from one another.

---

[*] With a personal grant from the Medical Research Council.

[†] A thin coat of any flat black-out paint, not water-soluble, is suitable.

[‡] This is strictly true in an energy–time diagram, and is almost exact in our temperature–time diagram because of the very small range of temperature involved.

We have so far omitted from our discussion the question of heat conduction by the air in the cradle. In fact, such conduction does take place, and even plays a considerable part in the heat transfer between cradle background and patient. The existence of this conduction, however, does not affect our conclusions, since there exists no direct heat conduction between the filaments of the bulbs and the patient, and heat conduction through air, as well as convection, takes place only between the cradle background and the patient. These effects are thus the same in the shielded and unshielded cradles.

Thus it appears that during the first few minutes the shielded cradle delivers rather less energy than the unshielded, but the amount of energy which can be delivered to the patient is very much greater in the former, since the conversion to long-wave radiation has already been carried out, whereas in the unshielded cradle the patient will only get what can eventually filter through a blanket.

The Physiological Action

The skin temperature of volunteers was measured in the two cradles. In each case a blanket was draped over the whole cradle and *the volunteer placed naked inside.* As was to be expected, the skin temperature rose in the first few minutes more rapidly in the unshielded cradle, but in both cases the same temperature (about 45° C.) was reached after about 15 minutes. While, however, this was very unpleasant under the unshielded cradle, no discomfort was felt in the shielded cradle. In the subsequent few minutes in the unshielded cradle first-degree burns developed, but no ill effects were suffered in the shielded cradle.

It is therefore clear that burning must be due to the direct radiation from the bulbs, which is present only in the unshielded cradle. As we have seen, this direct radiation forms a comparatively small fraction of the total heat output of the cradle, and it is evident that the burns are caused rather by the particular constitution of the direct radiation, which contains a certain amount of short-wave infra-red rays (0.4 to 4 μ), than by the amount of energy supplied. The shielded cradle emits thermal radiation with a maximum at 7 μ. It is not the total amount of thermal energy supplied by the unshielded cradle which limits its application, but the fact that the direct radiation from the bulbs can be tolerated by the skin for a comparatively short time only. This is, in fact, the reason why it has been found necessary to insert a blanket between the patient and the cradle. Though this acts as a convertor from short-wave to long-wave radiation, it cannot fulfil this purpose as efficiently as the blackened cradle background.

It was clear that the new shielded cradle could safely be used without protecting the patient with a blanket, while the old unshielded cradle could not. In order to test the efficiency of the two cradles as heaters a comparison was made between *the unshielded cradle with a single blanket over the patient and the shielded cradle with the patient naked.* In both cases blankets were draped over the whole cradle. Volunteers were placed in each of the cradles in turn on different days and heated with 12 bulbs until the oral temperature reached 100° F. or until the oral temperature remained constant for so long that it was clear that no further rise would take place. It was found that the best position was when the upper edge of the cradle was level with the lower end of the sternum. Observations of oral temperature and of skin temperature on the abdomen and thigh were made. Altogether 6 volunteers were heated, giving a total of 12 experiments. Two of the 6 cases were not conclusive. In one an oral temperature of 100° F. was reached in both cradles, and in the other this temperature could not be reached in either cradle. In the latter instance the cradle was placed considerably lower than the height which we have since found to be the optimum.

A typical result is shown in Fig. 4. In the shielded cradle the skin temperature rose to a roughly constant value of just under 45° C., although the temperature of the radiation field was almost double this. The oral temperature rose rapidly after about 30 minutes. In the unshielded cradle the skin temperature follows the same trend, but remains at a slightly lower level. The oral temperature could not be increased above 99° F. even by heating for 90 minutes. In this particular case the oral temperature reached 100° F. in the shielded cradle after 47 minutes' heating. This was almost the shortest time taken to attain this level with the shielded cradle, the shortest being 42 minutes.

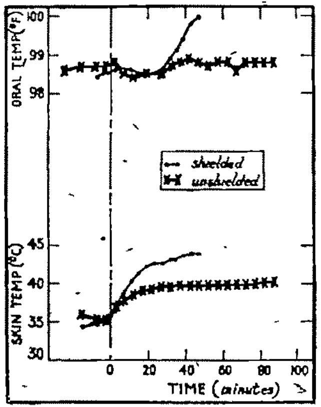

FIG. 4.—Oral and skin temperature of a patient heated in the two cradles. The shielded cradle is a more efficient heater owing to absence of necessity for skin protection.

It will be seen that there was a drop in the oral temperature after the cradle was switched on. This phenomenon occurred in both the shielded and the unshielded cradles. In 9 out of the 12 cases observed there was a decrease of oral temperature of 0.3 to 0.5° F., which took place in from 5 to 20 minutes after the heat was turned on, and thereafter the temperature rose steadily. The blood pressure, both systolic and diastolic, also fell slightly during the first 20 minutes. After that the systolic pressure and the pulse rate usually rose above the initial values; the diastolic pressure tended to remain low.

Comparing the two types, we find that the shielded cradle is definitely more efficient as a means of raising the body temperature than the unshielded. There is a very considerable scatter in the results, but we have plotted for each experiment a point representing the rise in body temperature during the experiment against the time for which the heat was applied (Fig. 5). The mean of all the shielded results falls well above the mean of the unshielded results, the slope of the dotted line in the former case being over twice the slope of the latter. All the inconclusive cases are included in this diagram—a representation which does less than justice to the shielded cradle, since an unshielded case in which the temperature refused to rise above a certain level would have been represented by a still lower mean rate of rise if the experiment had been continued longer.

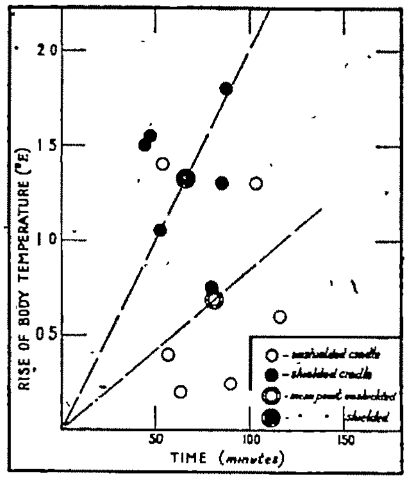

FIG. 5.—Rise of body temperature plotted against time of exposure for 12 experiments.

Even with the shielded cradle it was found that if the heating was continued at full strength for a considerable time a burning sensation was experienced and erythema developed. This is due to the fact that the cradle background gets steadily hotter and delivers a steadily increasing amount of energy; in fact, the system shows no sign of reaching equilibrium after more than two hours' heating. This means that under these conditions the patient is subjected to an ever-increasing flow of heat and that sooner or later the threshold for tolerance must be reached. The ideal situation would be one in which the patient received a constant flow of heat of tolerable strength. This can be achieved by switching off a number of the bulbs after an initial boost with 12 bulbs.

Investigations with a radiation meter were carried out in order to determine how many bulbs are needed to maintain a constant heat flow at various levels. Experiments were made by switching on 12 bulbs for a standard time (20 minutes) and then changing to the required number of bulbs. After falling for a short time the heat flow then became constant. For instance, when two bulbs only were left on after the boost, the temperature eventually fell and remained at 37° C. During the boost with 12 bulbs this level had been reached after about 8 minutes, and it was found that using 12 bulbs for 8 minutes and then switching to 2 produced the final equilibrium conditions in a few minutes, without at any time exposing the patient to more radiation than was needed.

Instructions for Use of the Shielded Cradle

It is suggested that the shielded cradle should be used by boosting for a certain time with 12 bulbs and then turning down the heating so as to maintain a heat flow of the desired strength. The accompanying table shows the times recommended for this procedure as suggested by these experiments (Fig. 6).

Boost Time with 12 Bulbs in Minutes	Final Radiation Temperature (° C.)	Number of Bulbs for Final State
8	37.0	2
12	47.5	4
32	63.5	6
60	73.0	8

It should be added that boosting with 12 bulbs for more than 40 minutes sometimes caused the patient's skin to become irritated. The kinder way is to apply 12 bulbs for 25 to 30 minutes, then 10 for about 20 minutes, and 8 thereafter. This is very little slower, and it causes far less discomfort. Irritation and erythema develop in the region of the groin at much lower rates of heating than anywhere else on the skin, and we have made it a standard practice to cover this region with a folded towel. To protect a restless patient from contact with the hot cradle we have used a guard of strong wire, similar to those ordinarily employed to lift the weight of blankets off the legs and feet. The wires of the guard were covered with two layers of white bandage, which kept it sufficiently cool, and distance pieces were fitted to hold the guard in the correct position.

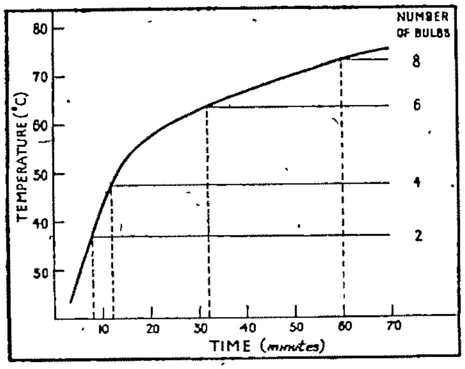

FIG. 6.—Chart showing boosting-times for the shielded cradle.

Some Further Investigations

A female patient suffering from arthritis was treated at various heating rates. Four experiments were made with 4, 6, 8, and 8 bulbs respectively, the boosting-times being regulated as above. Using 4 bulbs, the body temperature rose from 98.4° F. to 100° F. in 1 hour 55 minutes, including the boosting period. With 6 the rise was from 98.0° F. to 100.1° F. in two hours; with 8, rises from 99.5° F. to 101.8° F. in 1 hour 15 minutes and from 97.8° F. to 100.8° F. in 1 hour 35 minutes were secured. Thus the temperature can be raised quite comfortably at a fairly considerable rate. It immediately suggested itself that there might be a relation between the rate of rise of temperature and the heat input. The observational material was analysed by taking each period over which the heat input was constant and noting the rise of temperature in that time. The mean rate of rise was thus obtained for each heating rate, and from the observational records of this patient 8 points were obtained. A scatter diagram was plotted (Fig. 7), and it was found that all the points lay on a narrow band passing through the origin.

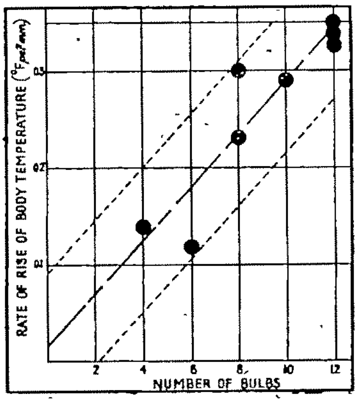

FIG. 7.—Diagram showing correlation between heat input and rise of body temperature.

While the results are certainly too scanty for a definite opinion to be formed, it is possible that such a correlation may exist for each individual case. If this is true a single determination of the rate of rise of body temperature at a given heating rate would form a valuable guide to the heat response and further treatment of the patient, since it would thus be possible to predict the rise in body temperature for any other heating rate. It should be noted, however, that the observed correlation relates only to the region between normal temperature and 102° F. and may not be continued to higher temperatures.

Discussion

This investigation was undertaken after two serious burns had occurred with the use of the Ministry of Home Security heat cradle. Questioning of senior sisters revealed no standard procedure in the heat-cradling of cold or shocked patients, and none was found in the literature. Aside from this lack of knowledge concerning the proper use of a powerful instrument, it was obvious that the cradle was needlessly dangerous, and that the customary procedure which made it tolerable—the protection of the patient by a blanket—greatly reduced its efficiency. Heat administration should be as carefully controlled as the administration of drugs or oxygen.

By simple modifications which a handy-man can carry out in an hour or so, a heat cradle has been devised which gives complete protection from early burns and which heats the patient much more quickly. The near infra-red component of the radiation has been converted with negligible energy loss to far infra-red, a type of radiation for which the skin has evidently a greater tolerance. This permits the withdrawal of the protection afforded by the blanket. The ability to control the dosage of heat accurately has resulted in the elimination of late burns, and is of obvious value in careful treatment. With the shielded cradle it is possible to expose the patient in a heat bath at any desired temperature without ever exceeding that temperature.

There remain certain dangers. With the unshielded cradle the risk of burning the skin, or actual burns, must often have prevented the introduction into the body of a dangerous amount of heat. When that costly safeguard is removed, more careful supervision of heat treatment is demanded. Under some conditions we have found that the patient's temperature rose at the rate of 2° F. in 20 minutes. This is a state which demands skilled observation, and we are firmly convinced that medical officers should supervise the use of the heat cradle more closely and not regarded it as an instrument which can be left without instruction to the nursing staff.

The question of the place of heat in the treatment of shock is made more urgent by the more efficient cradle. There is little doubt that it can be overdone. Blalock and Mason (*Arch. Surg.*, 1941, **42**, 1054) have found that exsanguinated and traumatized animals survive longer if they are cooled rather than warmed, and our own observations show that soon after the application of heat the blood pressure falls. Vasodilatation of the skin and enlargement of the vascular bed may well be harmful in shock. Some experimental work is being carried out to elucidate this point, but there is need for more observations on shocked patients.

Summarized Instructions for Use of the Shielded Cradle.—(1) Place the upper end of the cradle at the level of the lower end of the sternum. (2) Cover the cradle and its open ends with two blankets, and do not disturb these unless absolutely necessary. (3) Leave the patient naked except for a small hand towel to protect the groins, and if the patient is restless insert the guard (see above). (4) At first turn on all 12 bulbs. (5) After not more than 30 minutes reduce the bulbs to the number required to maintain the air temperature at the desired level (see Fig. 6). (6) Determine the oral temperature at least every 15 minutes.

Summary

The heat cradle issued by the Ministry of Home Security has been modified by shielding the bulbs and blackening the reflector.

As a result of the conversion of the short-wave infra-red radiation into long-wave infra-red the risk of burns is almost eliminated and the patient can be heated at least twice as rapidly.

The danger of overheating the patient is emphasized.

Instructions are provided for using the new cradle.

We should like to thank Prof. Witts for his interest and suggestions. Our thanks are also due to the volunteers who were used in the experiments, and to Mrs. V. Launchbury, who gave technical assistance.

SYPHILIS TREATED WITH DAILY MULTIPLE INJECTIONS OF MAPHARSIDE

BY

J. KVITTINGEN, M.D.
Surg. Lieut.-Cmdr., Royal Norwegian Navy

When Norway was invaded by Germany in April, 1940, a large part of the Norwegian Merchant Navy was isolated from its bases and eventually made its way to this country. In spite of dangers and hardships these ships continue their hazardous work, and it is not difficult to understand why, under prevailing conditions, the crews become easy victims to venereal disease when they are in port. There has been a serious increase in syphilis and other venereal diseases amongst the crews of these vessels; this constitutes a grave problem for the authorities at the present time and points to future difficulties in our social welfare. Before the war fresh cases of syphilis in Norway were very rare, and in 1938 there were only about 200 new cases amongst the whole population.

Routine treatment of syphilis is possible only if a sailor stays ashore for any length of time; but in most cases this cannot easily be arranged; and, furthermore, life ashore often has a demoralizing effect upon the men. Many who contract venereal disease come to the clinics only at irregular intervals, and treatment is necessarily unsatisfactory. These conditions obtain not only in the Merchant Navy but also in the smaller vessels of the Navy proper, and the smaller Army groups, none of which has a doctor on the staff.

At the beginning of 1942, following a review of syphilitic cases treated in the clinic, it was found that less than 30% of the patients were being adequately treated, and it was decided to start intensive arsenical treatment at the Norwegian Naval Hospital. Continuous intravenous drip therapy, using neoarsphenamine, has been tried in America (Chargin *et al.*, 1935), but the drug proved to be too toxic, peripheral neuritis being one of the most frequent complications. Later it was found that "arsenoxide" (mapharside), given in massive doses by the intravenous drip method, caused appreciably fewer toxic effects than neoarsphenamine (Chargin, 1940). Even so, the method presented difficulties, and massive arsenotherapy, using multiple-divided doses, eventually came into use. Gordon (1941), and later O'Malley (1941), in South Africa, employed a course of treatment consisting of five doses, each of 0.02 g., of mapharside at two-hourly intervals daily for a period of five days. At the same time 25 oz. of a 10% solution of glucose by mouth, spread over the day, were given during the period of treatment. Similarly, other workers in America have administered the drug by multiple doses, but, for the most part, have given two injections daily for a period of five days.

Method of Treatment

It was decided to follow the South African method, but to give larger doses of mapharside. On Feb. 2, 1942, treatment was begun, and by June 25 one hundred patients had completed the course. In this preliminary report consideration will be given to five groups of patients, all of whom have received the intensive course, special reference being made to the complications and reactions noted during treatment.

At the outset only untreated cases of syphilis in the first and second stages were given massive arsenotherapy. As the earlier patients tolerated the treatment so well it was decided to use the intensive method in cases in which either neoarsphenamine had been given previously and had not been well tolerated or the conditions were such that the patient was unable to follow routine treatment with weekly injections. Before starting the course the patients were carefully examined clinically and the urine investigated. On the day preceding the beginning of treatment each patient had an enema, and 300 to 500 c.cm. of glucose (6%) was given orally.

TABLE I.—*Scheme of Dosage*

Mapharside

	8 a.m.	12 noon	4 p.m.	8 p.m.
1st day	0·04 g.	0·04 g.	—	0·04 g.
2nd „	0·04 g.	0·04 g.	0·04 g.	0·04 g.
3rd „	0·04 g.	0·04 g.	0·04 g.	0·04 g
4th „	0·04 g.	0·04 g	0·04 g.	0·04 g.
5th „	0·04 g.	0·04 g.	0·04 g.	0·04 g.

Glucose Solution 6%

Daily for 5 days (total per day, 1,500 c.cm.):

7 a.m.	250 c.cm.	2.30–3.30 p.m.	300 c.cm.
8 a.m.	250 c.cm.	6–7 p.m.	200 c.cm.
10.30–11.30 a.m.	300 c.cm.	7–8 p.m.	200 c.cm

The total amount of mapharside administered over a period of five days was 0.76 g., but in the 83rd and subsequent cases each dose was increased to 0.06 g. on the third, fourth, and fifth days, making a total of 1 g. of the drug given during the five-day period. In the earlier cases the patients received 1,500 c.cm. daily of a 6% solution of glucose orally, and they were instructed to sip the solution over a period of one hour. When the dosage of mapharside was increased the amount of glucose was also increased to 1,800 c.cm. daily, in 6 doses of 300 c.cm. On the first day of treatment the 4 p.m. dose of mapharside was not given because this period of the day usually coincided with the time at which a Herxheimer reaction might occur. During treatment the patients were kept in bed and the urine was tested every morning and evening.

TABLE II.—*Complications and Reactions occurring in Five Groups of Patients*

Total	100	36	19	8	24	3	2	1	1	1	1

Results

Group I: Primary and Secondary Cases not Previously Treated.—In 36 of the 70 cases pyrexia occurred on the first day of treatment only. Occasionally the temperature rose to 103.4° F., but in the majority of cases it lasted only from three to five hours and did not exceed 100° F. Generally this increase in temperature caused no inconvenience to the patient and was so slight that it was recognizable only by taking hourly thermometric readings. Nausea, vomiting, and headache were experienced in those cases in which the temperature exceeded 100° F. One of the patients showed a trace of albumin in the urine on the last day of the course.

Group II.—These 10 patients had previously had one injection of neoarsphenamine at a clinic, where syphilis had been diagnosed. This group had no reactions or complication, with the exception of one patient (No. 82) who developed dermatitis and cerebral symptoms. Nevertheless, some of these patients had had a Herxheimer reaction before being admitted to this hospital.

Group III.—Five of the patients in this group were given intensive treatment with mapharside because they were intolerant to neoarsphenamine. The remaining 9 were unable to follow routine treatment with weekly injections.

Groups IV and V.—These two groups consisted of 1 patient with tertiary syphilis and 5 patients with latent syphilis.

Comments on Individual Cases

Case 7.—This patient had sero-positive primary syphilis. He differed from the other patients as he developed general lymphadenitis and exanthema macula papulosa; but recently he has been given a fresh intensive course of mapharside.

Case 13.—An initial course of neoarsphenamine was interrupted owing to dermatitis, nausea, and vomiting, and the persistence of severe headaches after each injection. On the completion of the course the patient developed jaundice. A fortnight after the jaundice had disappeared he was given a complete intensive course of mapharside without ill effects.

Case 19.—This patient had been given a course of neoarsphenamine in a V.D. clinic, but each injection was followed by severe vomiting, headache, and pyrexia. Towards the end of the course he developed a severe dermatitis with pyrexia, and was seriously ill for two weeks. After an interval of three months he was given a further injection of neoarsphenamine 0.3 g. and bismuth 0.2 g. at a V.D. clinic, but the dermatitis recurred. He came into this hospital a fortnight later and, although dermatitis still persisted, was given an intensive course of mapharside, which was completed without reactions.

Cases 35 and 96.—Both these patients were very sensitive to neoarsphenamine, and trouble occurred after each injection. One had previously had a course of mercury inunctions. This patient had slight vomiting on the first day of the intensive treatment with mapharside, but the other finished the course without reactions.

Case 63.—The first course of neoarsphenamine given at a V.D. clinic had to be interrupted several times owing to severe reactions following each injection. During treatment the patient lost weight and his condition deteriorated. A second course was started two months later, but again a severe reaction followed the first injection. He was admitted to this hospital, and the routine intensive course of mapharside was given. Slight vomiting occurred on the first day of treatment and the patient complained of headache, but he finished the course without further reactions until eight days later, when he developed jaundice.

Case 82.—The only patient amongst the series of 100 cases who had a serious reaction was Case 82, a rating aged 20 who had been exposed to infection about April 20. On May 25 he presented himself at a V.D. clinic on account of a penile ulcer of eight days' duration. *Spirochaeta pallida* was found by dark-ground illumination, and he was given neoarsphenamine 0.3 g. and bismuth 0.2 g. He reached this hospital about three hours after receiving the injections. On arrival he had a marked Herxheimer reaction. The presence of *Sp. pallida* was confirmed, and a blood test taken on May 27 showed a strongly positive Meinicke clarification reaction and a negative Wassermann. On May 29 the patient began intensive treatment with mapharside, the course being continued without reactions until the fifth day. That evening his temperature rose to 100° F., but he made no complaint and the full course was completed. On June 3 his temperature rose to 101.2° F. and he developed a morbilliform erythema. The temperature was 102° F. on June 4; during that day he complained of severe headache, and became more and more lethargic, and at times, confused. At 8.30 p.m. the same evening he suddenly shrieked and exhibited strong convulsions of the clonic type which lasted about three minutes. There were no further convulsions, but he remained unconscious until 10 a.m. the following day. During the next 24 hours the condition cleared up and the temperature fell to normal. The erythema which had made its appearance on June 3 disappeared 48 hours later, but severe headaches persisted for some days. The cerebrospinal fluid, collected shortly after the convulsions, was not under marked pressure, and contained 3 cells per c.mm. and protein 160 mg. per 100 c.cm. Gold test, 0012321000. The Wassermann reaction was very weak or doubtfully positive. On June 11 protein in the spinal fluid had decreased to 60 mg. per 100 c.cm. Possibly in this case the erythema was of a type that usually appears about the ninth day after starting arsenical treatment, and toxic encephalitis combined with this form of dermatitis is occasionally seen. Concerning the reaction in this patient it should be noted that the mapharside was dissolved in distilled water, which was almost certainly contaminated owing to a leakage in the distilling apparatus.

Serological Results

Thomas and Wexler (1941) found that on an average it requires 4 to 6 months after massive arsenotherapy for the blood Wassermann test to become negative, and in some instances it may be a year or more before complete serological reversal is achieved. According to these workers the longer a patient has had syphilis the longer it takes for the Wassermann reaction to become negative, although there are exceptions to this rule.

The serological findings for the first 100 cases in this series are shown in Table III. It has been the custom in this hospital to use the Wassermann and the Meinicke clarification reactions.

TABLE III.—*Serological Results*

Group	Total No.	Wassermann Negative			Meinicke Negative			Serological Relapse	Untraced
		Before Course	Immediately after Course	4 to 24 Weeks after Course	Before Course	Immediately after Course	4 to 24 Weeks after Course		
I ..	70	23	16	49	14	8	29	3	6
II ..	10	7	6	9	4	3	6	—	—
III ..	14	10	11	12	8	9	10	—	—
IV ..	1	1	1	1	1	—	—	—	—
V ..	5	3	2	2	1	—	—	—	—
	100	44	36	73	28	20	45	3	6

Among the first 100 patients there were 3 serological and clinical relapses.

Discussion

Experience in this hospital has demonstrated that *Sp. pallida* disappears from the chancre in less than 24 hours after treatment with mapharside. Primary and secondary lesions heal very quickly. In no instance during treatment of these 100 cases has there been any difficulty in giving 19 injections over a period of five days. Only males have been treated, and in many cases the patients also had gonorrhoea. With one exception there have been no serious reactions, and in most cases pyrexia occurred only for a few hours on the first day. The procedure has been to dissolve the mapharside in redistilled sterile water in the proportion of 0.01 g. in 1.5 c.cm., according to the number of cases to be treated. With this intensive treatment it is necessary to have nurses who are acquainted with the procedure, and the patients should be under their constant observation.

Summary

A series of 100 cases of syphilis treated with multiple injections of mapharside is described.

The first 82 cases received 0.76 g. of mapharside within a period of five days. The remaining 18 received a total of 1 g. during this period. These injections were combined with the oral administration of glucose.

The reactions, which with few exceptions were mild, are described. Only in one case was there a serious reaction.

This series of cases is too small for any definite statement to be made regarding this method of treatment, but these results indicate that in a time of emergency massive arsenotherapy is of the utmost value, although the method is fraught with more risk than the orthodox treatment.

I wish to express my appreciation of the services of my assistant, N Bonsaksen, and the nursing staff of the hospital.

THREE COMMENTS ON THE PREVENTION OF STERILITY

BY

E. SCHLEYER, M.D.

The falling birth rate is giving rise to serious concern, and many committees and societies are studying its causes. Sterility is of course one important cause. Special sterility clinics have been formed for the purpose of examining and treating sterile couples, but those seeking advice are established cases of sterility, only some of which can be cured. Most investigations dealing with sterility have been concerned with its causes and treatment, but my object is to indicate the importance of its prevention. Three conditions which may lead to sterility are here discussed—namely, hypoplasia of the uterus, gonorrhoea, and chronic constipation.

Hypoplasia of the Uterus

There are two types of hypoplastic uterus. In the first of these, in which the foetal form is maintained, the cervix is longer than the fundus, the uterus is acutely ante- or retroflexed, the os is pin-point, and the tubes are usually tortuous. Owing to the persistence of a foetal condition this may be called *primary hypoplasia,* and it is due to insufficient stimulus of the gonadotrophic and ovarian hormones. Hypofunction of the thyroid may also be a causative factor. In the second type the uterus presents the adult differentiation but is smaller than normal (*secondary hypoplasia*). It develops only in adult life following amenorrhoea, severe illness, or prolonged feeding of a baby when the mother is not in good health. It is an atrophic condition of the uterus, and its main symptom is sterility.

The chief sign of primary hypoplasia is disorder of menstruation. The menses usually begin regularly but become infrequent and scanty, and finally cease. Some patients may have scanty periods at one time and profuse at another. Dysmenorrhoea is also very common in hypoplasia. Sterility usually follows, and is to be attributed to causes such as insufficiently developed endometrium or anovulatory cycles, ectopic pregnancy, or abortion.

In the adult woman primary hypoplasia is rarely curable. It is important, therefore, that the condition should be recognized in time, and proper measures taken to correct the faulty development. Any abnormalities of menstruation at puberty and during adolescence should receive serious attention, since they may be danger signals showing that development is not progressing normally (Kurzrok, 1937). Every girl who has not established a regular, normal, and relatively painless menstrual habit before the age of 15 needs inquiry into her general health and endocrine condition. The secondary form of hypoplasia might be prevented by adequate treatment of amenorrhoea and removal of the causes leading to the atrophy of the uterus.

At the present time, when thousands of girls still in their teens are engaged in war work, special attention should be given to these questions. Medical officers should be trained to recognize the early symptoms of endocrine disorders. The influence of every kind of war work on young girls should be studied. The experience of the last war showed what harmful effects improper feeding might have on young people. Spaeth (1917) and Vaerting (1918) have observed atrophy of the internal genital organs in women who, not properly nourished, were exposed to severe factory conditions. An adequate quantity of protein and vitamins is most important.

Gonorrhoea

It is well known that sterility may follow gonorrhoea, but since the discovery of the sulphonamide group of drugs the treatment of the latter has been revolutionized. Nowadays acute gonorrhoea can often be cured in a few weeks, but this advantage may be offset by the danger of overlooking slight inflammation of the Fallopian tubes, a lesion which may show no acute symptoms but may be the cause of later sterility if neglected.

The first case I observed was that of a young woman of 29 who contracted acute gonorrhoea. She underwent a course of treatment with sulphapyridine, and became negative to tests within three weeks. She was kept under observation for another two months, after which she married. Three months later she returned seeking advice because no baby was yet on the way. Examination by tubal insufflation revealed blockage of both Fallopian tubes. There was no sign of inflammation, so two weeks later I carried out another insufflation, during which the pressure, which first rose to 200 mm., suddenly dropped to 110. This suggested that the tubes had become patent, evidence for which was also provided by the fact that the patient complained of shoulder pains. Three weeks later she became pregnant. This is one of several cases in which I have found blockage of the tubes three to six months after acute gonorrhoea. It looks as if the gonococci, having lost their virulence owing to the chemical treatment, may cause only a slight inflammation of the tubes, which heal up in such a way that the walls adhere together slightly without being blocked. Under those conditions insufflation, performed in time, may prevent definite blockage and consequent sterility. King (1939) expressed the view that the sulphonamide group of drugs are not directly lethal to the organisms, but modify their metabolism so that the body defences are enabled to get the upper hand. Similar inflammatory reactions are observed in the prostatic gland after chemotherapeutic treatment (Lloyd, 1939; R. Lees, 1939). I would therefore suggest that no woman with gonorrhoea should be declared cured until the tubes have been examined. If they should be closed within three to six months after apparent cure then repeated tubal insufflation should be performed. The first insufflation should not be made before the third month and not later than the sixth month after the last negative specimen. Before performing the insufflation the following precautions should be taken: (1) the cervical secretions must have been free from gonococci for at least three months; (2) the blood sedimentation rate must be normal; (3) there should be no detectable sign of inflammation of the tubes; (4) there should be no focal or general reaction after the provocative treatment with gonococcal vaccine.

Constipation

After a special study (Schleyer, 1937, 1938) of the interrelationship between the pelvic colon and rectum and the female genital organs I reached the conclusion that inflammation of the rectum and pelvic colon may spread to the pelvic organs, leading to salpingitis and salpingo-oophoritis. One of the most common causes of proctitis and sigmoiditis is chronic constipation. Habitual disregard of the call to defaecation results in blunting of the sensation for defaecation and to accumulation of faecal masses in the rectum and sigmoid. This stagnation leads to damage of the mucous membrane and dilatation of the lower bowel, so that intestinal bacteria may invade the tissues and cause inflammation of the intestine. The anatomical situation of the lower intestine makes it possible for this inflammation to spread to neighbouring organs and thus cause salpingitis. Salpingitis often ends in sterility. Prevention of constipation and proper treatment of procto-sigmoiditis may thus be important factors in the prevention of sterility.

Summary

Sterility is an important cause of the falling birth rate. Once established it is difficult to cure, but prevention is sometimes possible. Three conditions are described which may lead to sterility—hypoplasia, acute gonorrhoea, and chronic constipation. Timely treatment of each of these might lessen the danger of subsequent sterility.

Medical Memoranda

Haemothorax due to Strangulated Diaphragmatic Hernia

Haemothorax as the predominant clinical sign following acute strangulation of a diaphragmatic hernia is unusual enough to warrant record.

CASE HISTORY

The patient, a farm labourer aged 37, gave a history of previous good health, although he had complained to his family of occasional indigestion. On Jan. 14, 1942, he felt severe abdominal pain immediately after supper. He was seen by one of us (S. M. S.), who found him shocked and restless, with temperature 97°, pulse 100, and respirations 20. There was tenderness on deep palpation below the left costal margin but no rigidity. Dullness with diminished air entry was found at the left base, suggesting effusion. He was neither dyspnoeic nor cyanosed. He had been sick once, the vomit appearing normal.

He was admitted to Evesham Hospital on Jan. 15, and at 11 a.m., because the physical signs indicated a rapid increase in the amount of fluid and his condition was deteriorating, an exploratory needle was introduced into the fifth space in the left mid-axillary line, and 10 c.cm. of normal-looking venous blood was withdrawn. A radiograph of the chest revealed that the heart and mediastinum were well over to the right, and there was a dense uniform opacity over the whole of the left lung field. When seen by another of us (S. D.) on the 16th the patient was orthopnoeic and had begun to vomit a little blood. The physical signs all pointed to the thorax: abdominal examination did not suggest anything abnormal there. 27 c.cm of apparently normal venous blood was then removed from the chest. A second radiograph taken immediately after this showed that the heart and mediastinum were still over to the right; no fluid was now apparent on the left side, although there was diminished translucency. In the upper part of the left lung-field could be seen what appeared to be a loop of intestine, and irregular opacities were noted immediately above the left diaphragm. The left lung was collapsed against the mediastinum. At this stage the patient was seen by Dr. Haslett of Cheltenham, who diagnosed a ruptured diaphragmatic hernia. The patient's general condition deteriorated rapidly, the respiration rate rose although the vomiting became less frequent, and he died in the early hours of Jan. 16.

Necropsy.—This was performed 36 hours after death. On opening the chest it was noticed that the left lung was collapsed. This collapse was old-standing. The pleural cavity was occupied by a mass of blood clot and what turned out to be omentum. In addition there was a loop of gangrenous stomach which had herniated through the diaphragm with a portion of omentum. The right lung showed oedema of the base and a little emphysema at the apex. The hernial orifice was well up towards the mesial attachment of the muscle in the oesophageal opening. The herniated portion of the stomach was in the form of a well-marked diverticulum. No gross ulceration of vessels could be found in the stomach wall, and there is little doubt that there had been a generalized oozing from the strangulated portion of the stomach and omentum. Histologically the mucous membrane of the stomach was necrotic, but there was a distinction between the abdominal and thoracic portions, the glandular structure being preserved in the former, although nuclear staining was imperfect, while in the latter the mucosa had virtually gone, the whole appearance being one of necrosis with extravasated blood extending throughout the wall. At the point of strangulation there was considerable fibrosis of the stomach wall. Sections through the neck of the strangulated portion of the omentum (which weighed 148 g.) showed arteries and veins to be distended with blood clot; in some instances organization had started, but the nuclei of the adipose cells had disappeared, as had also an appreciable proportion of the cells of the vessel walls. There was diapedesis through the damaged vessels, and altered blood pigment was found in the adipose-tissue spaces.

DISCUSSION

We have been unable to find a parallel case in the literature. Blood in the pleural cavity was noted, but only as a fortuitous finding by Alderson (1858), Boysen (1921), Schaper (1925), and Collier, Hurst, and Sheaf (1929). In our case the haemothorax was presumably due to a diffuse oozing from the gangrenous mesentery and incarcerated portion of the stomach, but one or more vessels of larger calibre may have contributed towards the haemorrhage. In this connexion Knaggs (1904) stated: "The ulceration that occurs in strangulation of the stomach seems to be different from ulceration in strangulation of the intestine. In the latter it begins on the mucous membrane surface and extends to the outer coats. In the case of the stomach the available evidence points to extreme distension producing splits through the peritoneal and muscular coats, perforation being staved off for a time by the integrity of the sodden and rotten mucous membrane. Further, ulceration does not appear to have been noted at the seat of constriction, the most common place for it in the intestine."

Jankelson and Morein (1940) have enumerated the pre-operative and post-operative complications of diaphragmatic hernia. Anaemia, they claim, is frequent, and is due to repeated small haemorrhages or oozing from congestion or erosions of the mucous membrane of the lower oesophagus or stomach. Profuse haemorrhages originating from multiple fissures in the constricted portion of the stomach have been observed gastroscopically by Jankelson. Other complications are rupture of oesophageal varices, oesophageal or gastric ulceration, diverticulation, and carcinoma. In addition, volvulus would appear to be a not infrequent cause of incarceration, and in our case torsion of the herniated portion of stomach and mesentery may have contributed to the fatality.

The victims of diaphragmatic herniation thus go through life with many potential dangers threatening them, and it is pertinent to ask if, when discovered by routine examination (and by mass radiography!), they are to be subjected to surgical operation for repair. Our patient's congenital weakness of the diaphragm might have been disclosed earlier had his dyspepsia been investigated radiologically, but his symptoms were of so slight a degree as not to cause him to seek medical advice.

Pfeiffer's Bacillus Meningitis: Recovery after Sulphapyridine

Before sulphonamide therapy, meningitis due to Pfeiffer's bacillus had a very high mortality rate, especially in children. Aleman (1940) collected records of 478 cases in infants aged 2 years or under. The mortality rate was 97%. Sulphanilamide only slightly improved the figures—82 cases, with 87.8% mortality (Aleman, 1940). But sulphapyridine has given much better results, and Mitchell (1941) found records of 33 patients who recovered after treatment with it: 16 of them had received specific serum also, and 10 of the 33 were aged 30 months or less.

The following brief report shows certain interesting features of a case treated with sulphapyridine: (1) the ease with which a high sulphapyridine level in the C.S.F. was obtained, (2) the high degree of tolerance of the drug; (3) the relapsing of meningitis.

CASE RECORD

A boy aged 3 was playing in the garden on the morning of May 28, 1942, and ate his dinner normally. In the late afternoon he was found in convulsions in his pram. He had never been ill before and was an only child. Both parents were healthy. When seen he was almost comatose, and was twitching constantly. Apart from slight neck rigidity, physical examination was negative. The C.S.F. was turbid and contained many polymorphs. Sulphapyridine was started. Phenobarbitone soluble, gr. 1/2 by injection, was necessary to control the fits. Next day Pfeiffer's bacillus was grown in the C.S.F. The sulphapyridine dosage was 4 g. in 24 hours—one 0.5 g. tablet every 3 hours.

After 48 hours the temperature, which was 102.4° F. on admission, reached normal, and he seemed quite well apart from some neck stiffness. On the third day the C.S.F. still showed Pfeiffer's bacilli on culture and 8 mg. of sulphapyridine per 100 c.cm. The drug was continued. Next day only one colony was grown from the C.S.F., in which the sulphapyridine level was 11 mg. per 100 c.cm. Neck rigidity remained and sulphapyridine was continued for 8½ days, the C.S.F. level on the last day being 5.8 mg. The total dosage was 23.75 g. A blood count on the fifth day showed 4,000,000 red cells, 76% Hb, and 14,500 white cells, of which 70% were polymorphs. On the ninth day the C.S.F. was turbid but sterile, and contained 65 cells per c.mm. (50% polymorphs and 50% lymphocytes) and 40 mg. of protein per 100 c.cm. He was discharged on the sixteenth day, having been clinically normal for 6 days.

Next day he was brought back with neck rigidity and a temperature of 101.4° F. The C.S.F. was turbid, and contained 2,600 cells per c.mm. (50% polymorphs and 50% lymphocytes); its total protein was 70 mg. per 100 c.cm., and it was sterile on culture. He was given another course of sulphapyridine, the total dosage being 10 g. in 3½ days. His temperature was normal the following day and has remained so. 20 days after the initial onset the C.S.F. was clear and colourless and contained 25 cells per c.mm. (90% lymphocytes); total protein 25 mg. per 100 c.cm., chlorides 760 mg.; sterile on culture. He was then quite normal and has continued so. There was no evidence at any time of sinusitis, otitis, or upper respiratory infection. No vomiting occurred throughout the illness.

Reviews

TREATMENT OF WOUNDS AND FRACTURES

Wounds and Fractures. A Clinical Guide to Civil and Military Practice. By H. Winnett Orr, M.D., F.A.C.S. (Pp. 227; illustrated. 27s. 6d.) London: Baillière, Tindall and Cox.

The Winnett Orr method is now firmly established in surgical practice in the treatment of chronic osteomyelitis and infected compound fractures. The author of the method has been preaching and practising his principles since the last war, but it is only during the last ten or fifteen years that the method has been widely tested and proved. The two essentials in treatment are that effective immobilization of the limb must not be prejudiced by the presence of an open discharging wound and that meddlesome interference with the wound should be avoided by the "no dressings" technique of the closed plaster.

The first section of the book deals with these fundamental principles of the Winnett Orr method and describes in detail the technique of its application. In the treatment of compound fractures a wound excision is performed in the usual manner, the fracture is reduced accurately on a fracture table, and a plaster cast is applied. Two pins, one above and one below the fracture, are incorporated in the plaster to obtain complete immobilization of the fragments, and vaseline gauze is used to dress the wound. The plaster is closed and there need be no interference to inspect and dress the wound unless pain, swelling, or a raised temperature occurs. The author stresses the importance of a thorough preliminary excision; and in the case of wounds already infected and in osteomyelitis adequate drainage must be ensured by the operation before the closed plaster is applied.

The succeeding chapters deal with special problems in fracture treatment which illustrate the application of the Winnett Orr method. Fixed skeletal traction by means of two or more pins figures prominently in the cases illustrated, but wiring and plating of the fracture itself is not advised. No attempt is made to deal systematically with the whole field of fracture treatment, and the cases are chosen largely for their value in illustrating the principles which the author seeks to emphasize. The book is written in a dogmatic fashion, and some of the statements made would be better if they had been qualified in some way. For instance, in the very short section on fractures of the spine it is stated that if the fracture is reduced at once in anatomical position "symptoms of cord injury may be expected to disappear at once." Surely even the Winnett Orr method cannot do this.

The book is well produced and illustrated by a large number of photographs and *x*-ray pictures. Each of the chapters is written round a small collection of selected clinical cases chosen to illustrate views expressed, and this makes the book very practical and readable.

THE LABORATORY RAT

The Rat in Laboratory Investigations. By a staff of Thirty Contributors. Edited by John Q. Griffith, jun., M.D., and Edmond J. Farris, Ph.D. (Pp. 488; illustrated. 45s.) Philadelphia, Montreal, and London: J. B. Lippincott. 1942.

This book deals fully with the rat and its behaviour under normal conditions and under all types of laboratory experimentation to which it has yet been subjected. Probably no other animal has been used in such large numbers or for such a variety of purposes, which is chiefly due to its size and ease of handling, its readiness to eat nearly anything (but in quantity only sufficient to satisfy its hunger), and its speed in reproduction. The editors of this book even claim that the rat "can be readily standardized," which suggests that rats can be expected to respond in equal degree to the same treatment. This is far from the truth; the variation between individuals, even within the same litter, is always large and sometimes appallingly so. Hence large groups of rats are used and comparisons drawn from average results whose reliability may be estimated statistically.

The different chapters in this book have been written by different specialists. They deal with breeding of the rat (and housing, etc.), general methods (of handling for injection, etc.), gross anatomy, experimental methods and rat embryos, dietary requirements, teeth, digestive system, metabolism, central nervous system, techniques for the investigation of psychological phenomena, circulatory system, use of the rat in biological assay of hormones, doses of drugs for rats, haematology of the rat (methods and standards), radiological considerations, surgery of the rat (23 operations), histological methods adapted for rat tissues, the osseous system, the eye of the albino rat, protozoan parasites of the rat, metazoan parasites of the rat, spontaneous diseases of laboratory rats. Each chapter has its own bibliography, and there is a good index; the book contains 1,863 references (unfortunately those for the chapter on the digestive system (1-11) are missing). The diagrams, photographs, and *x*-ray plates are excellent. All experimenters who work on rats will wish to have access to this book and will find in it much of interest on their own subject and much that will be enlightening on subjects of other workers.

PHYSIOLOGY FOR MEDICAL STUDENTS

Handbook of Physiology and Biochemistry. By the late W. D. Halliburton, M.D., LL.D., F.R.C.P., F.R.S., and R. J. S. McDowall, M.D., D.Sc., F.R.C.P.Ed. 37th edition. (Pp. 977; illustrated. 21s.) London: John Murray.

As indicated by the author and on the cover, this book is primarily and essentially meant for the use of medical students. Consequently it could not be expected to be deep or exhaustive in any senses of these terms, and, in fact, it is not. It would be expected to be as clear as possible and as accurate as its brevity would allow, and for the most part these merits must be conceded, though in places it bears marks of slipshod handling. This is perhaps to be attributed to the acknowledged impossibility of any one man being a master of the whole subject, though it often seems that the hapless student is expected to have such knowledge. However, the student's object is to pass his examination, and the author's to put him wise to the task. The long-continued success of this work as a student's book is proof enough that mutual satisfaction has been reached. In future editions it may be worth the author's while to alter Figs. 101 and 104, which depict neurones without cell bodies—a dangerous seed to sow in the mind of a candidate—and we would be glad to see Fig. 197 a little modified too. The index is helpful and complete and the paper and general get-up are of the best.

Notes on Books

To mark the bicentennial conference of the University of Pennsylvania, the University Press have published a pamphlet on ***Problems of Intestinal Obstruction*** (Philadelphia: University of Pennsylvania Press; London: Oxford University Press, 1941, pp. 56; 3s. 6d.). It consists of four papers: the first, on electrolyte balances in the obstruction of the gastro-intestinal tract, is by Dr. J. P. Peters, the John Slade Sly Professor of Internal Medicine at Yale. The next, on distension in intestinal obstruction, is by Owen H. Wangensteen, the second edition of whose book on intestinal obstruction we recently reviewed (1942, 2, 696). Decompression of the intestinal tract is discussed by W. O. Abbott of the University of Pennsylvania, while A. O. Whipple and J. A. Nelson are joint authors of the last paper on the end-results of decompression of the intestinal tract with and without operation. Such problems as transperitoneal absorption, the systemic effects of obstruction, and the effects on the intestinal wall of sustained distension are considered. Expressions like "scout radiographs of the abdomen" (Section III, p. 31) are perhaps rather unusual to us, but how much more graphic is this one than the straight or plain "*x*-ray" which we have been accustomed to ask for? Most abdominal surgeons will value this little book. It is unfortunate that its attractive appearance in clear type on matt paper is marred by the fact that the pages have been put together in wrong order. This should obviously be corrected if, as we hope, a reprint is called for.

The National Baby Welfare Council has just published a leaflet, "The Stammering Child and How He can be Helped," priced at 2d. per copy or 1s 9d. a dozen. Another of the Council's leaflets, "Should we have a Baby in Wartime?" is sold at 2s. per hundred copies. Orders for both leaflets should be sent to the N.B.W.C., 29, Gordon Square, London, W.C.1.

Nova et Vetera

BODIES FOR DISSECTION IN DUBLIN IN 1818

We are indebted to Dr. W. B. Heywood of Newbury for the sight of an interesting letter written in beautiful handwriting by Dr. John Cheyne (1776-1836) to Dr. Edward Percival, son of Thomas Percival, the Manchester physician and author whose *Medical Ethics* is still a book well known in professional libraries. John Cheyne was one of the founders of the Dublin School of Medicine and his name is linked with that of William Stokes in "Cheyne-Stokes respiration." The letter, written from his house in Merrion Square, Dublin, on Dec. 2, 1818, is too long to quote in full. It is largely concerned with the morbid appearances in cases of fever during one of the frequent epidemics. Discussing the post-mortem findings Dr. Cheyne writes:

> "From Macartney's habits of careful observation, I receive his statements with confidence, but I cannot help objecting to the source from which he derives his information, which he says was obtained from an examination of the subjects who were brought into his Theatre with Petechiae on the surface. By the way Petechiae were as rare in the winter as they were common in the summer and autumn, and some kinds of Petechiae can scarcely be distinguished from flea bites. But as the mortality among the poor during the winter was chiefly caused by the Epidemic I am willing to allow that these subjects were really victims of fever. But still I allege that they were not calculated to afford a fair representation of the havock of that disease on the human frame, and the process of disinterment, when explained, will show that my objection is not frivolous.
>
> "The Bodies used in most of the dissecting rooms are derived from the great cemetery for the poor called the Hospital Fields—vulgo Bullys Acre; these, there being no regular resurrection men, are procured by the pupils who, fixing upon a grave, are influenced by the appearance of fresh earth scattered around it, by the freshness of the sods if there are any, and by the looseness of the substratum of soil, which is probed by a pointed iron instrument called 'a poker.' But notwithstanding great enterprize and exertion and disregard of danger which sometimes is also great, the work being done by amateurs, and not by regular members of this part of the profession, disappointments ensued, and the subjects raised were often in an advanced stage of putrefaction and certainly the dissecting rooms are often supplied with bodies which have been under ground for a fortnight or three weeks. In the work of exhumation the upper part of the grave is cleared, the corresponding part of the lid of the coffin is torn up, and then by means of a noose round its neck the body is extracted by main force. The bodies tied up in a sack, neck and heels, are subject to great violence during their transport from the Burying ground—as for example, they are dropt from a high wall, by which as is well known fractures of the cervical vertebra not unfrequently occur. To conclude, the cadaver is roughly handled in the dissecting room, being often left with the head hanging over the table, by which means the blood gravitates and *congestion* of the brain to a great extent is the consequence. With regard to the colour of the intestines I rather think, when putrefaction is advanced, extravasation takes place and a more uniform dark colour than natural. From the foregoing account which is not exaggerated it may be affirmed that the condition of the capillary system cannot well be learnt from an examination of the bodies which are usually brought into a public dissecting room.
>
> "As to our own proceedings at the House of Industry from which conclusions so different have been drawn. The body is removed to a deadroom in a coffin—the dissection is made in almost every instance within 24 hours after the patient's death and the particulars of the dissection are committed to writing as a sequel to the case which generally is regularly reported."

HISTORY OF BLOOD TRANSFUSION

A note on the history of blood transfusion by Eric L. Cooper (*Austral. New Zeal. J. Surg.*, 1941, 11, 84) reminds us that it is not a modern innovation. In 1490 three small boys gave their blood, at the rate of 10s. a head, to Pope Innocent VIII. All three donors died, but whether their blood was actually transfused is doubtful, Dr. Cooper believing that the patient probably drank a mixture containing blood and stimulants. In 1615 Andreas Libavius, and in 1653 Robert des Gabets, a monk of Cluny, described procedures for blood transfusion. In 1657 Christopher Wren and Robert Boyle tried the effect of injecting various substances into the veins of animals. Then, in 1665, Richard Lower, at Oxford, successfully transfused blood from one animal to another by joining the vertebral artery of the donor to the jugular vein of the recipient. Jean Baptiste Denys, in Paris, is said to have been the first to transfuse blood into a man when, in 1666, he injected 9 oz. of lamb's blood into the veins of a youth suffering from a prolonged fever. A year later Richard Lower transfused the blood of a lamb into a Mr. Arthur Coga, with the result that he "kept back impending insanity." After his fourth patient to be transfused had died as the result of an incompatible transfusion, Denys was charged with murder, but was acquitted, the Parlement of Paris forbidding further experiments on human beings. A Papal Edict in 1675 forbade the further transfusion of blood. Work on blood transfusion then had a setback for a hundred years, and towards the end of the eighteenth century interest was revived by, among others, Erasmus Darwin, the grandfather of Charles Darwin. Matters were carried much further by the eccentric James Blundell, who was obstetrician and anatomist at Guy's and St. Thomas's. In 1818 he invented a syringe with a three-way tap for direct transfusion. It is interesting to recall that in 1857 Higginson performed seven successful transfusions with the syringe which still bears his name. Virchow and Bischoff, in 1835, had used defibrinated blood, and this was subsequently also used at Bart's in 1873 by Thomas Smith. Attempts were made to delay clotting by adding ammonium sulphite in 1867 and sodium phosphate in 1868. A turning-point in the history of transfusion was the introduction of paraffin-coated transfusion apparatus. Then, in 1915, citrated blood was used for the first time. Apart from the prevention of clotting, the other essential step to make blood transfusion safe was taken when Landsteiner, and also Shattock, in 1900 demonstrated the presence in the blood of iso-agglutinins and established three blood groups, to which a fourth was subsequently added.

TWO PIONEERS OF AMERICAN MEDICINE

Doctor Bard of Hyde Park · The Famous Physician of Revolutionary Times, the Man who Saved Washington's Life. By John Brett Langstaff Introduction by Nicholas Murray Butler. (Pp. 365. $3.75.) New York · E. P. Dutton & Co., Inc. (302, Fourth Avenue, New York, N.Y.).

There were two Dr. Bards—John the father and Sam the son—both of them outstanding men of their time; and while this volume chiefly deals with the latter, there runs through it a constant reference to Dr. John Bard, the father, who set himself to elevate the medical profession in America. He founded the American Medical Society and became first Health Officer of New York. In the eighteenth century quack doctors, who were his pet aversion, "abounded like locusts in Egypt: they were mere pretenders to a profession of which they were entirely ignorant." Dr. John Bard, born in 1716, lived 83 years, and was proud of the achievements of his son Dr. Sam Bard, who is the subject of this biography.

In 1761 Sam embarked for England. On reaching London he studied anatomy under William Hunter and then went north to Edinburgh, where he became a distinguished student and medallist, graduating in 1765 and returning to New York a year later. During these years the father's enthusiasm was a constant spur to his son's activities. When Sam came back his father handed over his practice, the foremost in the city, and retired to the family estate of Hyde Park. The next 40 years were for Dr. Sam Bard full of social, cultural, and political activities, but he ever kept the advancement of scientific medicine in the forefront; he even found time for study and the writing of books and monographs. He lived in the stirring historical period of the American Revolution and the Declaration of Independence. He worked hard to found the New York Medical School (Columbia University), which four years later had the distinction of granting the first American degree of M.D. He organized other scientific societies, founded a State medical library, and inaugurated the New York Hospital.

Sam Bard was the Osler of his day, and the same could be said of his father. The author, Mr. Brett Langstaff, spent six years of research in compiling the biography of these two eminent eighteenth century doctors. American readers will find this book intensely interesting: British readers also will enjoy its quaint lore and historical accuracy. The book is a model of how a medical biography should be written.

C. J. Brim (*Arch. Derm. Syph.*, Chicago, 1942, 45, 371) suggests that Job's illness, which has been variously identified with syphilis, leprosy, and other skin conditions, was really pellagra, and draws attention to the similarity of the symptoms in Job's case with that of a typical example of the disease.

LONDON
SATURDAY JANUARY 16 1943

TREATMENT OF MALARIA UNDER WAR CONDITIONS

With the Allied armies operating in many tropical and subtropical malarious countries and the certainty that men from these armies will return infected to this country, not to mention other sources of malarial infection brought about by the war, it may be taken as certain that many medical men who have never had anything so far to do with malaria will find themselves called upon both to diagnose and to treat this disease. To make things more difficult, the old and familiar quinine salts so long used in this connexion will, from lack of adequate supplies, almost certainly under present conditions have largely to give place to treatment by new and unfamiliar synthetic compounds. Ideas of treatment, too, have changed a good deal lately, and drug prophylaxis has assumed an importance which it never before had. Yet, all things considered, the treatment of malaria in recent years has become much simplified. Indeed, treatment and prophylaxis of malaria are in practice by no means so complicated as the mass of detail in the literature might lead the beginner to suppose. In relation to the war there are short helpful pamphlets issued by the War Office[1] and the Ministry of Shipping[2] relating to Army treatment and malaria among seamen respectively. Recently a paper read before the Royal Society of Tropical Medicine and Hygiene by Sir Rickard Christophers,[3] the President, has dealt with the elements of treatment in special relation to the use of the new synthetic drugs. We may note also a paper read at the same meeting by Major T. Rowland Hill, R.A.M.C., dealing with malignant tertian (*falciparum*) malaria among troops engaged in military operations.[4]

What, then, are the chief points the beginner should know? In the first place it is necessary to distinguish between treatment of an attack of malaria and so-called prophylaxis or, more correctly, drug prophylaxis. The only drug for both treatment and prophylaxis, apart from quinine, is the synthetic drug mepacrine (the pharmacopoeial name for atebrin). This is the only completely satisfactory substitute that will in practice be available. Mepacrine is a British-manufactured drug. It is made available in two forms—namely, the drug as ordinarily used in small tablets of 0.1 gramme, and as an extra-soluble form in ampoules for injection. Mepacrine is not to be regarded as a mere second-best substitute for quinine. It is a drug as potent as, if not more so than, quinine, and it is one that can be used safely and even with some advantages over quinine. In all cases in which there is no serious reason to the contrary, both with quinine and with mepacrine, administration should be by the oral route. Another British-manufactured drug, pamaquin (the pharmacopoeial name for plasmoquin), is likely also to be available, but it is not a substitute for mepacrine or for quinine and is now not used alone either in treatment of the acute attack or in prophylaxis. It is thought by many to aid treatment by reducing the liability to relapse or to be an adjuvant in after-treatment and prophylaxis. This need not unduly concern the beginner, for it cannot be said that pamaquin is a necessary drug in the sense that mepacrine is, and its use can be left to be decided upon as experience may suggest. Pamaquin is much more toxic than mepacrine, and is used in doses not exceeding 0.02 gramme often combined with quinine (quinoplasmin, etc.). It should not be given at the same time as mepacrine but may follow or alternate with this. The curative dose of mepacrine—i.e., the dose used in treatment of an attack of malaria (we refer only to the adult dosage)—is 0.3 gramme taken in three spaced doses (three 0.1-gramme tablets) a day, preferably after food (or with milk), as there is a slight tendency to minor gastro-intestinal symptoms. Usually after a mild purgative this dosage is begun early and continued for seven days. If the fever has not subsided by the end of this period it is to be suspected that some other condition than malaria is present. The reasons why administration is not continued in any one course for a longer period than seven days are (1) that it is not necessary, and (2) that mepacrine has a rather marked cumulative effect. There is no objection, however, to a repetition of such a course after an interval, say, of a week's time.

This simple procedure constitutes the essentials of the treatment of a malaria attack—namely, the temporary destruction of the parasites. It is very doubtful whether with either mepacrine or quinine more prolonged treatment at this time will effect any more complete destruction, and one must trust ordinarily to treating as a further attack any relapse which may subsequently develop, though something may be done in the way of after-treatment to reduce the chances of this. Much attention has been given to methods of reducing liability to relapse by after-treatment. But without invaliding to the base or home it is not very probable that in war conditions much more than treatment of attacks as they occur and the usual prophylactic dosage can be carried out in the field. Quinine is sometimes used to start a treatment by mepacrine, and many modifications have been recommended by different authors, but these again are a matter for personal predilection and experience. One consideration in treatment is very important and requires constant vigilance and prompt action: this is, when dealing with *falciparum* infection, to anticipate the onset of coma or other pernicious manifestation indicating serious danger of death. *Falciparum* infection, or so-called malignant tertian, is the common malarial infection contracted by Europeans in the Tropics. In spite of the name attacks are not necessarily severe, but the parasite has the property not possessed by any other malarial parasite of giving rise, often rather suddenly or insidiously, to pernicious manifestations the normal end of which, unless promptly countered, would be death. The indication in such an event is to get the specific drug at all costs at once into the circulation, and it is usually taught that an immediate injection should be given intravenously, this being the quickest known route of administration. Intramuscular injection is also recommended by some authorities, but in the case of quinine there is a divergence of opinion. With mepacrine the local necrotic effects produced by the quinine salts usually used appear to be absent, and intramuscular injection, which need not be into the gluteal region, has been widely employed and apparently without objectionable effects. If intravenous injection is difficult, intramuscular administration of mepacrine may therefore be substituted, but intravenous injection is perhaps more rational and better practice. The precaution should be taken to inject slowly.

The usual prophylactic dose of mepacrine is 0.2 gramme (two 0.1-g. tablets) a day, given on two successive days each week. This is roughly the equivalent of the usual 5 grains of quinine daily. As pointed out by Major Rowland Hill in the paper referred to above, malaria has often decided the course of a campaign, and the only practicable way to prevent malaria where troops are operating in the face of the enemy is drug prophylaxis. It is therefore vital that this should be appreciated by all, including the ranks themselves. In our present armies the intelligence of the private soldier is high, and his education and instruction in self-protection should be more effective in bringing about the desired result than reliance solely on the old and very imperfect mechanism of the quinine parade. Mepacrine in certain amount produces a yellow coloration of the skin. This is quite harmless and merely due to the colour of the dye. It is in no way related to jaundice, nor is it evidence of constitutional disturbance. Some harmless temporary yellow coloration, even if it affected every individual in the Force, would be a small price to pay for immunity to malarial attack and success of a campaign which might otherwise have failed.

AGAINST TETANUS

Passive immunization of the wounded man with tetanus antitoxin served us well in the war of 1914-18. This method is still current in the German-controlled areas, but in most of the Allied armies active immunization is now the custom. The technique of active immunization is not yet uniform. British authorities and the American Army use formol-toxoid; the American Navy favours tetanus alum-toxoid, which has remarkably high immunizing potency. All give at least two injections about a month apart. In the English Army immunization is voluntary. Most armies practise re-immunization, and it is understood that the British give further injections at intervals. The Americans re-stimulate with a third dose of toxoid after six months or before embarkation or entry into active fighting, and periodically thereafter. Practice also differs somewhat when the wounded soldier first comes under medical care. The British give a prophylactic injection of tetanus antitoxin to all accessible wounded irrespective of previous immunization. The Americans and Canadians trust to the rapid increase of immunity after an "emergency stimulating immunization" with an extra dose of toxoid, reserving antitoxin for the treatment of clinical tetanus.

To what degree are our men protected against tetanus? The experience of the B.E.F. in Flanders and France was suggestive. The published figures show that some 80 to 90% of about a quarter of a million men had received immunizing injections of tetanus toxoid. Among the 10 to 20% not immunized, 8 cases of tetanus occurred during the Dunkirk period; there were no cases among the immunized. As no method of active immunization gives absolute protection against the highest possible risk, it is reasonable to expect an occasional case of tetanus in the present heavy fighting, and, according to Col. Boyd,[1] cases have occurred. His paper will be studied with much interest. The outstanding points are clear. Tetanus is rare in the Middle East fighting zone, but the risk is there, for in wound swabs from 494 soldiers not suffering from tetanus 2 cultures of tetanus bacilli were found. Among large forces from the United Kingdom, India, and New Zealand, who were the most highly immunized, the incidence of tetanus was 0.13 per 1,000 wounded; among the South African Forces, among whom immunization was not in vogue in the early part of the war, the incidence was 1.6. The figures are small—11 British cases with 4 deaths, and 7 prisoners of war with 5 deaths—but, analysed in every way, they "afford evidence of the value of inoculation," though 5 actively immunized men suffered and 3 died. None of the 5 had, on being wounded, received the prescribed dose of prophylactic antitoxin. There was no convincing evidence for or against the utility of chemotherapy.

We do not know what precisely is the complex relation in the immunized animal between the toxin of the developing tetanus bacillus on the one hand and the antitoxin-producing cells and the highly receptive local nerves on the other. It is easier to understand what happens in the unimmunized animal when in the laboratory toxin is injected into the tissues. The dose of toxin is limited and is not being added to continuously by fresh toxin made by the living bacillus. If the animal thus injected with diphtheria or tetanus toxin has in its blood sufficient antitoxin to overwhelm and neutralize the whole of the toxin, it does not suffer any ill effect. But if it has no antitoxin or an insufficient amount, the toxin at once attacks or is absorbed by the cells susceptible to it. We know from the timed-Schick-test experiments of Glenny and Hopkins[2] in guinea-pigs that some of the toxin is attached to the cells in thirty minutes, for no amount of antitoxin after that time will prevent some small reaction in the skin. After three to six hours all the toxin is absorbed by the susceptible cells, for even a large excess of antitoxin injected intravenously will not avert the appearance in due course of a full-sized Schick-positive reaction. Similarly, if a fatal dose is injected subcutaneously it is all absorbed within eight to twelve hours, and death will occur despite huge amounts of antitoxin injected intravenously.

In the immunized animal conditions are more complex Zuger[3] and his co-workers have studied what happens when tetanus spores and irritant are, later, injected. They protected guinea-pigs by two spaced doses of tetanus alum-toxoid. After intervals of some months they injected a lethal mixture of tetanus spores into immunized animals. The group of animals thus treated possessed considerable immunity, for only 17 of 76 showed symptoms of tetanus, though the dose of spores was sufficient to kill all of 20 unimmunized control guinea-pigs. Into 75 immunized guinea-pigs there was injected an additional dose of tetanus toxoid at the same time as the tetanus spores; the effect of the additional toxoid was apparently to reduce the incidence of tetanus, for only 8 of the 75 developed local, non-lethal tetanus. In the immunized animal infected with tetanus spores, toxin may be formed slowly or rapidly, depending on the amount of injured or necrosed tissue and on the intensity of infection. If it develops slowly, as it presumably did in Zuger's experiments (for 64% of his animals did not develop rigidity until the seventh day), the production of antitoxin by the appropriate cells, trained to their work by the original immunization, may be moderate or great. An additional dose of immunizing toxoid given at the time of infection or wounding apparently much hastens and magnifies the production of antitoxin, but this process may not operate quickly enough to overwhelm toxin generated immediately after the injury. In Boyd's apt phrase, the toxin outpaces the antitoxin. Zuger's results and Boyd's cases are consistent with the deduction we can draw from the earlier experimental work. This strongly indicates that the fate of the infected immunized animal depends primarily on the amount of antitoxin ready formed and present in the circulation at the time of infection. This antitoxin is ready to seize on and neutralize the first toxin produced.

Experience of passive immunization in the American Fourth-of-July tetanus campaign and in the war of 1914-18 indicates that a dose of 500 to 1,500 units of tetanus antitoxin (=1,000 to 3,000 international units) gives high protection against tetanus. After this quantity the blood shows an early concentration of about 0.1 to 0.2 unit per c.cm. This titre has been aimed at by many investigators of active immunization, though figures ranging from 0.01 (Boyd[4]) to 5.0 (Peshkin[5]) are found in the literature. Evans[6] found that most of his adults four months after immunization against tetanus had more than 0.01 unit per c.cm., and Marvell and Parish[7] found 0.1 unit or more in 40 of 61 people bled about six weeks after two spaced doses of tetanus toxoid. The immunologist would expect titres of this kind to confer solid protection. Yet Zuger's figures make us pause. Of 49 immunized guinea-pigs with more than 5 units at the time of injection of spores, one which received no additional toxoid developed general tetanus and 4 suffered from local tetanus. For further evidence we must await further experience. Meanwhile two clear conclusions emerge. We must aim at the highest possible concentration of tetanus antitoxin in the blood of every soldier exposed to risk; this can be attained by periodical re-stimulation with tetanus toxoid of all soldiers; the argument for giving prophylactic antitoxin to wounded men seems at present cogent. With regard to surgery, Boyd, like all with experience, stresses the paramount call for immediate and adequate surgical attention to damaged or necrosed tissues. Naturally, these same lines of argument are in general applicable to gas gangrene.

COLLAPSE AND BRONCHIECTASIS

The finding of bronchiectasis in association with pulmonary collapse has given rise to much speculation on the nature of the relation between these two conditions. Tannenburg and Pinner[8] have produced collapse of a lung in rabbits both by means of a rigid bronchial plug and by bronchial ligation, and they have studied the condition of the bronchi in lungs so collapsed. They found that the first change after the bronchus had been blocked was rapid deflation of the lung owing to absorption of its contained air. This phenomenon was first demonstrated by Lictheim[9] in 1879, and it is interesting that Tannenberg and Pinner found that the lung could become completely collapsed in less than 20 minutes. The bronchi took part in this process and were at first constricted. In the absence of infection the lung could remain in this condition for many weeks, but in most animals the bronchi in the collapsed lung were found at necropsy to be dilated and full of muco-purulent secretion. Sections of the bronchial walls showed them to be thinned and infiltrated with inflammatory cells but not ulcerated. The introduction of infected material into the bronchus before ligation produced gross septic bronchiectasis with ulceration and destruction of the bronchial walls. Removal of the bronchial plug after 7 to 10 days usually resulted in complete re-expansion of the lung with restoration of the bronchi to their normal condition. These authors conclude that the chief factor which causes bronchiectasis in collapsed lung is infection. If this is mild the bronchi are merely distended with exudate and not damaged; but if severe an irreversible deformity results. As they obtained similar results in the presence of a pneumothorax they state that the negative pressure in the thorax is not a factor in the production of bronchiectasis. This explanation is probably true of those cases in which a large bronchus is firmly and completely obstructed, but such an occlusion is comparatively rare in the human subject. Instances are common in which bronchography has demonstrated bronchiectasis in a collapsed lobe very shortly after the occurrence of the collapse, thus showing that the bronchus supplying the lobe is not obstructed but widely open and dilated. Some other explanation must be found for these cases, and that advanced by Lee, Lander, and Davidson,[10] [11] and also by Andrus,[12] seems the most probable. These authors consider that the obstruction in such cases is due to a plug of viscid secretion which is sucked gradually out towards the periphery until it finally becomes split up into a number of tiny plugs which occlude the finer bronchioles. These effectively prevent aeration, and the lung remains collapsed. The large bronchi in the collapsed area are not cut off from the outside air and are subjected to atmospheric pressure, while the negative pressure in the thorax is increased owing to the shrinkage of the lung. This suction is transmitted directly to the bronchi through the inelastic collapsed tissue around them and therefore they dilate.

Thus it seems that in those instances of pulmonary collapse in which there is not complete obstruction to the main bronchial supply the collapse is probably due to peripheral obstruction, and bronchiectasis is caused by the increased negative pressure in the thorax. On the other hand, in those rare instances where the main supplying bronchus is completely occluded the bronchi are at first constricted, owing to the absorption of the air within them, but later become distended with inflammatory exudate. In both conditions severe infection may ensue and cause a permanent bronchiectasis by ulceration of the bronchial walls

JAUNDICE AND YELLOW FEVER VACCINE

The occurrence of jaundice in patients a considerable time after they had been inoculated with a yellow fever vaccine and immune serum was described by Findlay and MacCallum[13] in England in 1937 and by Soper and Smith [14] in Brazil in the following year. The available data indicated that the disease was not yellow fever in any form. It was later suggested by Findlay and MacCallum[15] that the causative agent of this condition might have been a virus which was present in the human serum used either for growing or suspending the virus or in the immune serum inoculated with the vaccine. Both the above groups of workers restarted their cultures with a clean strain of virus, and all serum used was heated for at least 30 minutes at 56° C. No further cases have followed the use of vaccine made in England since November, 1937. After over a million people had been inoculated in Brazil the condition reappeared again in October, 1939, in about 27% of a group of 304 persons all inoculated by Fox *et al.*[16] with one lot of vaccine about four months previously. In May, 1940, more cases appeared, related to a small number of different lots of vaccine. Out of approximately 107,000 people injected with the incriminated batches there were 1,072 who became icteric after an incubation period of 12 to 20 weeks. The most recent and astounding example of this phenomenon occurred in 1942, when 28,585 cases with 62 deaths were reported[17] in the American Army after the use of a similar vaccine. Clinically many of these cases closely resemble those of infective hepatitis (catarrhal jaundice), but in the latter the incubation period is usually between 20 and 32 days in contrast to that of 8 to 20 weeks in the post-inoculation cases. In earlier reports,[18] in spite of the difference in incubation period, it was suggested that these two conditions might be caused by the same virus, but the accumulation of information as a result of these recent large outbreaks has provided evidence of a much greater incidence of joint pains and skin lesions of different types than have been recorded in infective hepatitis. Fox and his colleagues also noted a much higher incidence in the older age groups in their vaccinated population. Fortunately all information available at present indicates that in the average patient hepatic damage is slight and repair prompt and complete. As the tendency is to incriminate the human serum used for suspending the virus in the vaccine, the serum has been eliminated from use in both North and South America, and the vaccine is now merely an extract of finely ground infected chick embryos diluted with distilled water. A somewhat similar condition occurring in children after the use of measles convalescent serum and adult serum was described by MacNalty[19] in 1937 and Propert[20] in 1938. There was a long incubation period of 8 to 12 weeks, followed by hepatitis of varying severity but in general more serious than in the post-vaccine cases. This latter may have been the result of the very much larger quantity of serum which the children received. Neither in this instance nor in the use of vaccine in England or in South America was there any history of jaundice in any of the donors of the serum. The view that this condition is caused by an infective agent has not as yet received any experimental or clinical proof. All attempts at animal transmission have been unsuccessful, and there have been no recorded instances of suggestive contact cases except by Propert. The view that the disease is caused by the action of some toxic agent or peculiar property of certain human sera receives some support from accounts of similar happenings in horses many weeks after the inoculation of horse serum in immunization against horse sickness,[21] equine encephalomyelitis,[22] and anthrax.[23] It is desirable that physicians should make sure that their cases of so-called catarrhal jaundice may not have some other origin.

LIVER PUNCTURE

The differential diagnosis of hepatomegaly or jaundice rests only too often on the results of laparotomy or the findings at necropsy. Cullinan[24] has pointed out that there is very considerable risk that death may follow from haemorrhage or liver failure if the abdomen is opened in subacute necrosis of the liver. Iversen and Roholm[25] have recently elaborated a method of liver biopsy which enables them to study the histology of the liver during life without opening the abdomen. A liver puncture is made with a trocar through the 9th intercostal space and a column of liver tissue is obtained by aspiration. The specimen is one to two centimetres long and about two millimetres in diameter. The procedure itself is usually painless, though a few patients experienced severe pain, and two had minor reactions with sweating, pallor, and nausea. Two also had a rise of temperature lasting a day or two. The real danger of the method lies in the risk of haemorrhage. Iversen and Roholm record no fatalities in 116 aspirations, but at necropsy on one patient with obstructive jaundice, who died 9 days after the puncture, 1½ litres of blood-stained fluid was found in the peritoneal cavity, and in another there was a large clot at the site of the puncture. Baron[26] and Köfler[27] have also used liver puncture but prefer a subcostal approach, as they consider there is less danger of bleeding from capsular tears. Baron had one fatality from haemorrhage, and in one case a piece of colonic mucous membrane was aspirated, although, surprisingly, no evidence of perforation could be found at operation. Köfler used both methods of approach, and among 100 aspirations there were two deaths from haemorrhage.

Although this is obviously a risky method of investigation, it has proved to be of real use. Roholm and Iversen[28] studied infective hepatitis, obtaining a clear picture of the histology at all stages of the disease where jaundice was present. They found well-marked inflammatory changes with destruction of the trabecular structure and disintegration of the parenchyma cells. There was a varying amount of proliferation of the connective tissue, which in three cases suggested a cirrhosis. The interlobular bile ducts were unaffected. Köfler confirmed their findings. Roholm and Krarup[29] studied the changes in obstructive jaundice. Obstruction due to gall-stones or to cancer caused the same type of change. Cirrhosis was late in appearing and was marked only after the 180th day of jaundice. In cholelithiasis the changes subsided rapidly if the jaundice was of short duration. Baron showed that this method was also useful as a purely diagnostic procedure. Among 18 cases of hepatomegaly he was able to prove secondary carcinoma in 12 cases, and to diagnose such comparative rarities as congenital cystic disease and cavernous angioma as causes of enlarged liver. Aspiration failed to reveal carcinoma in only two cases in Baron's series, although Iversen and Roholm recorded 22.5% of aspirations as complete failures. The risk of haemorrhage appears to be highest in severe anaemia and haemorrhagic diathesis, and here liver puncture should be avoided. The tendency to bleed in obstructive jaundice can be overcome by the use of vitamin K. In spite of its dangers, this seems to be a really valuable procedure, which could throw new light on the development and pathology of many obscure conditions.

THE PRIME MINISTER'S PHYSICIAN

All members of the profession will wish to join us in congratulations to Sir Charles Wilson on the high honour conferred upon him by the King. His services to medical education and in particular to St. Mary's Hospital are widely recognized, and his acute and alert mind must be of benefit to the House of Lords. But the appreciations printed so far have scarcely touched upon the outstanding fact that the President of the Royal College of Physicians of London, now in his second year in that chair, is the personal physician to Mr. Churchill and as such has flown with the Prime Minister to at least three far-distant Allied capitals on missions of great consequence to the united war effort. The elevation of Sir Charles Wilson to the peerage may well be regarded as a public acknowledgment not only of his merit as an adviser on medical policy at No. 10, Downing Street, but also, and far more important in these momentous times, of his value to our country and our allies in safeguarding the health and energy of the statesman who leads and personifies the British will to victory. This is a very responsible key post, though unmentioned in the official New Year Honours list, and no praise or reward can be too high for its successful holder

"Aids to the Investigation of Peripheral Nerve Injuries" is the title of M.R.C. War Memorandum No. 7, compiled by the Nerve Injuries Committee of the Medical Research Council (H.M.S.O., York House, Kingsway, London, W.C.2; 2s. net). After a short introduction of a page and a half the remaining 46 pages consist of photographs and diagrams designed to show those "less experienced in the examination of patients with lesions of peripheral nerves" how to diagnose these. This admirable atlas has been prepared by the staff of the Department of Surgery, University of Edinburgh.

CONTINUING RESEARCH ON CANCER

The nineteenth annual report of the British Empire Cancer Campaign is less bulky than its predecessors, but in smaller type it gives probably the same amount of information. It was presented to the annual general meeting of the Campaign on Dec. 15, the Duke of Gloucester presiding. Reports from some twenty-four research departments or branches of the Campaign in this country and eleven over-seas, as well as from a number of individual workers, are embodied. The Campaign has spent £100,000 since the war began, and has subsidized to the fullest extent every associated research centre.

Nutrition in Relation to Cancer Incidence

Bittner found that there exists in the milk of female mice of high-breast-cancer strains a factor concerned in the development of spontaneous breast cancer. In the Department of Experimental Pathology and Cancer Research of the University of Leeds this observation has been used in studying the effects of oestrogenic stimulation upon male mice. The newly born young of high-breast-cancer strain were transferred as soon as possible after birth to mothers of low-breast-cancer strain, and vice versa, and in the young males after weaning injections of triphenylethylene were made and continued until death. The results so far indicate that there is an almost complete reversal of the expected incidence of breast cancer in the treated males. Of the mice which have died only one high-breast-cancer mouse suckled by a low-breast-cancer foster-mother developed breast cancer, whereas all but three of the low-breast-cancer mice suckled by a high-breast-cancer foster-mother have died of breast cancer. The untreated female litter-mates have also been observed, and again the effects of deprivation of the milk factor are very marked. In another laboratory, at the Royal Victoria Infirmary, Newcastle-upon-Tyne, by fostering mice of low-cancer strain on females of high-cancer strain, the incidence of mammary carcinoma in the former has been raised from about 5% to nearly 60%.

Again at Leeds an attempt to induce lung cancer in mice by intranasal administration of methylcholanthrene and 1:2:5:6 dibenzanthracene has produced an interesting and unexpected result in the appearance of breast tumours in several of the experimental animals, and when pure inbred strains were used it was found that mammary cancer occurred in two strains in which it had not been known to occur spontaneously. It is suggested that the most probable explanation is that the carcinogen reaches the breast via the nipple and exerts a genuinely local effect on the mammary epithelium.

Other work on carcinogenesis comes from the Sir William Dunn School of Pathology at Oxford, where it has been shown that there are substances which, although incapable of producing the pre-carcinogenic state, are yet capable, when applied to skin already rendered neoplastic by other means, of precipitating the development of papillomata, and also, when allowed to act on papillomata already established, of facilitating their conversion into malignant tumours. It seems, therefore, that carcinogens may be resolved into three independent components, and the substances concerned in the process may be divided into "complete" carcinogens, when they are able to induce all three actions (that is, pre-, epi-, and meta-carcinogenic), and "incomplete" carcinogens when, like croton oil, they can induce only one of the processes. The existence of "incomplete" carcinogens may have important clinical implications.

A very interesting piece of work in general pathology comes from the Glasgow Royal Cancer Hospital. Last year two workers there reported that rats fed on an adequate basal diet to which heated lard was added developed vitamin A deficiency and papillomatosis of the fore-stomach, a lesion which could be prevented or cured by the addition of raw carrot to the diet. It has now been shown that similar protection is afforded by adding cod-liver oil, and further that the change from white bread to national bread has stopped the occurrence of gastric papilloma in rats on a diet poor in vitamin A.

Clinical Research

Finally, passing over much other work of interest, including progress in the correlation of the quantities of energy involved in the medical use of different types of radiation, a further detailed analysis by the Clinical Cancer Research Committee of the Campaign is given. This year it concerns 473 cases of carcinoma of the oesophagus registered in London hospitals during 1938 and 1939, together with a brief review of 65 cases of post-cricoid carcinoma. Figures are given showing the site of the disease, the stage to which it had advanced on admission to hospital, the procedures used to confirm the diagnosis, the treatment, and the results. The first symptom was dysphagia in 67% of the cases; in the remainder, misleading symptoms led to mistakes in diagnosis. In only 5 cases was radical surgery possible. An analysis shows the high mortality of exploratory operations and the operative risks of intubation or dilatation. The results of radiation treatment were disappointing. Of the 65 patients with post-cricoid cancer, 56 died in the first year from the beginning of treatment, 3 died in the second year, and 1 in the third; 2 of the remaining cases are known still to be alive and 3 are as yet untraced. Of the 473 patients with carcinoma of the oesophagus, 399 died with cancer in the first year, 19 in the second year, and 5 in the third. A significant point is the sex difference. Of 65 cases of post-cricoid cancer, 54 (83%) were in females, whereas of 473 cases of oesophageal cancer only 76 (16%) were in females. The mean age of the post-cricoid cases was 65 years for males and 55 for females, and that for the oesophageal cases, 64 for males and 61 for females.

MEDICAL VISITS TO AFRICA AND MALTA

Dr. A. G. H. Smart, medical adviser to the Colonial Office, who has recently returned from the Middle East, and Dr. W. H. Kauntze, assistant medical adviser, who had previously during the year visited Africa, have given brief accounts of their tours to the Colonial Advisory Medical Committee.

Dr. Smart told the committee that one of the main reasons for his visit was to inquire on behalf of the Secretary of State into the welfare and state of health of the people in each territory after the strain occasioned by three years of war. Another was to satisfy himself that liaison between the Services and civil authorities was as complete as possible. He had since reported fully to the Secretary of State on these two aspects of his visit. He dwelt on the position that he had found at Malta, where his visit coincided with the arrival of a food convoy. One thing that had impressed him very much during his tour was the whole-hearted devotion to duty that was apparent everywhere, and he noted how in this effort, as in this country, women were taking a prominent place.

Dr. Kauntze told the committee something of his tour, which occupied six months and covered most of tropical Africa He, too, had certain specific objects in mind during his visit on which he was able to give some information to the committee. Among other things he found that great progress had been made in maternity and child welfare work, more especially in East African territories. He also noted developments in the organizing of dispensaries as welfare centres in West Africa and mentioned the need for an increase in numbers of subordinate staff with better facilities for training. He also spoke of the advance which had been made in medical education at Makerere College in Uganda, and at the Yaba Medical School at Lagos, Nigeria.

INDUSTRIAL MEDICAL SERVICES IN WARTIME

A special meeting of the Association of Industrial Medical Officers was held recently, to which representatives of the Royal College of Nursing, the Association of Examining Factory Surgeons, and the Association of Scientific Workers had been invited, to discuss industrial medical services in wartime.

In opening the discussion Dr. M. W. Goldblatt, who presided, said that planning was necessary both in allocating medical man-power for the industrial medical service and in determining the status and duties of medical officers once they had entered it. Practical schemes for dental and ophthalmic services in industry, the provision of suitable canteens, the training of first-aid personnel, and the education of the worker in elementary principles of hygiene were all matters which should occupy the new medical officer's attention. Sir David Munro pointed out that it was the duty of the industrial doctor to see that we were able to use available labour most economically and avoid wastage by ill-health and accident Dental, ophthalmic, *x*-ray, and rehabilitation services were all necessary to this end. He would like to see an Institute of Industrial Medicine established which would become a centre of research, particularly into toxic substances. In time industrial medicine should have its own diploma. Mrs. A. Perry, S.R.N., said that the scope of the industrial nurse varied in different factories according to the size of the medical department. In a large factory with its own doctor the nurse should be responsible to him, and should enjoy a status equal to that of the welfare officer and personnel assistants. In the smaller factory she should be responsible to the managing director, and could, in many cases, if trained accordingly, combine the duties of nurse and labour officer with considerable advantage to everyone. Dr. J. H. Humphrey of the Association of Scientific Workers said that at present 75% of the workers were in factories of fewer than 1,000 persons and were unlikely to have any industrial medical service. He asked to what extent the results of experience in industrial medicine and hygiene were being recorded and what statistical skill was being brought to bear on them. Dr M. W. Paterson spoke of the good work done by the first-aid personnel, who knew conditions in their own factory and had the confidence of their fellows in the early treatment of the industrial injury. But the existing instruction manuals, he said, were inadequate and present methods needed to be completely revised. Dr. E. H. Strange had found that hygienic conditions in canteens were often bad. The proper washing of dishes and utensils and the control of waste should, he said, be among the matters which the industrial doctor should observe when inspecting a canteen. In the discussion which followed, Dr. Tom Garland said it was clear that the present industrial medical services were inadequate and should be expanded to cover all workers, especially those in the small factory, and that to achieve this State control was necessary.

Reports of Societies

NEUROLOGICAL COMPLICATIONS OF MALNUTRITION

At a meeting of the Section of Neurology of the Royal Society of Medicine on December 17 a short discussion took place on the neurological complications of malnutrition.

Dr. V. P. Sydenstricker, who is in this country with the U.S. Army, spoke on nicotinic acid deficiency, adding that the influence of the deficiency of other vitamins of the B group was not known, though probably all were implicated. The neuropathic symptoms were not specific; they might resemble neuroses of almost any type as well as the ordinary functional and toxic psychoses. Partial deficiency of nicotinic acid caused deviations which at the time were mild but led on to serious anatomical changes. Lassitude, slight mental deterioration, and loss of memory for recent events were common; insomnia, headache, and paraesthesia were also noted, and characteristic glossitis and dermatitis might make their appearance. A large number of patients who were treated before nicotinic acid became available were definitely psychotic, and in severe cases of long duration the cure did not follow even prolonged nicotinic acid treatment. In some patients stupor alone was found on admission to hospital, but "cart-wheel" rigidity afterwards developed. The management of these states was very simple. The patient should be fed during the first few days on a liquid diet of milk, eggs, and cereal gruels, given by stomach tube if necessary. It was often possible to add marmite to the liquid food. Some improvement was shown in the majority of patients within 48 hours of beginning treatment. Not all instances of delirium, mania, and hysterical manifestations seen in acute infections or in post-operative states were due to avitaminosis, any more than all stuporous states found in elderly people were due to that cause, but it always seemed worth while to investigate the matter and to give nicotinic acid psychosis a place in the diagnostic list.

Dr. H. M. Sinclair said that almost every member of the "vitamin band wagon" had been incriminated in discussing the origin of peripheral neuropathies. Ten or fifteen years ago it was demonstrated that degeneration of the central nervous system could be produced in animals on diet deficient in vitamin A, and it was suggested that a large number of neurological conditions in man were due to this cause. If vitamin A deficiency were established in animals at a sufficiently early age skeletal growth stopped, but the growth of soft tissues, including those of the central nervous system, continued, so that there was overcrowding of the cranial cavity and relative overgrowth of the tissues. It seemed a reasonable conclusion on the basis of recent work that the nervous lesions in vitamin A deficiency were wholly mechanical in origin. In the case of vitamin E most workers were now agreed that there was very little evidence of its importance in preventing neuromuscular disease. On the use of vitamin B_1 for different forms of peripheral neuritis a voluminous literature had grown up, but it had recently been suggested that it would not stand critical review. If he might summarize the position rather dogmatically, it appeared that some types of polyneuritis were accompanied by deficiency of vitamin B_1, and the same was true of some cases of the polyneuritis of pregnancy. Arsenic and alcohol inhibited utilization of the vitamin. In the peripheral neuropathies, while deficiency of vitamin B_1 no doubt played an important part, it was not the only factor.

Identifying the Vitamin

Dr. R. M. Stewart, who presided, said that the clinician's difficulty was that very often in these mild states of malnutrition he did not know which deficiency to claim. Clearly in wartime the absence of several vitamins might be cited. During the last war he saw a number of Bulgar prisoners of war among whom there were a very large number of cases of scurvy. On investigating them from the neurological standpoint he found certain abnormal signs due to the presence of very large haemorrhagic extravasations, although in other cases there were very few indications beyond subjective sensory symptoms associated with diminution or loss of ankle-jerks, sometimes bilateral. It seemed to him that it must be very difficult to know, without some saturation test, which vitamin was concerned. The *Journal of the American Medical Association* had recently declared that scrutiny of the life-history of some patients and studies of their personality showed that the earliest effects of nutritional deficiency were not to be found in the polyneuritis of beriberi, the bleeding gums of scurvy, or the dermatitis of pellagra, but rather in mental deterioration, nervous instability, and other forms of vague ill-health, which almost always came first. It seemed rather extraordinary that it should be the brain which first manifested the symptoms of vitamin deficiency when they could all recall cases of illness arising from this cause in which there was no mental change throughout.

Dr. Russell Brain referred to a group of patients, mostly women, who were brought to hospital after having lapsed into coma at home for no obvious reason, who showed no obvious signs, and in whom, after death, no neurological change was discovered. Another group consisted of alcoholics who passed into coma after a history of head injury, not of a severe nature. In such cases he had thought of subdural haematoma; but on making an exploration no such condition was found.

Correspondence

Pasteurization of Milk

Sir,—Judging by three of the letters in your issue of Jan. 9 the answer to the question, "Do doctors disagree about pasteurization?" is that they are too imperfectly informed on the subject to be entitled to any opinion at all. The impartiality with which you ventilate opinions contrary to the declared policy of the Association is commendable, but I doubt whether this licence, fashionable though it is in the present mood of this country, should be extended to misstatements of fact. According to Dr. Eric Coldrey (p. 52), "Most people define pasteurization as the raising of milk to 150–160° F. for 20 minutes." Pasteurization by the holder process is officially defined as maintaining milk at a temperature of 145–150° F. for 30 minutes. That this process can be depended on to kill tubercle bacilli and all other agents of milk-borne infection is an incontestable fact, and Dr. Coldrey's opinion and experience have no weight against it whatever. The thermal death-points of bacteria are not a matter of opinion; they are well-ascertained facts. Either the milk supplied to his patients was inefficiently pasteurized, or—which is very likely—they drank raw milk at some period not covered by his inquiries, or they acquired their infection from some other source. Dr. A. H. Macdonald (p. 52) offers us the information that tubercle bacilli and "99% of other pathological germs" get into milk "largely through dung and dirt." This is simply not true. Tubercle bacilli in milk are derived from lesions in the cow's udder, typhoid bacilli usually from the hands of a milker who is a carrier or from contaminated water used for washing pails or churns, and the streptococci which cause epidemics of milk-borne scarlet fever usually from the throat of a milker. Of what worth is Dr. Macdonald's opinion if it is founded on fancies such as this? The idealism of Dr. E. K. Mackenzie (p. 52) is in a different category, but has he any conception of the holocaust by which alone the elimination of infected cattle is immediately feasible, of the ruin which it would bring to the dairying industry, and of the disastrous effect on food production, all perfectly unthinkable at such a time as this? Even in times of prosperity and plenty the eradication of bovine tuberculosis must be a colossal task occupying many years. Are we not entitled in the meantime to demand that milk shall be made safe by pasteurization?

The producer-retailer and the small dairy which cannot afford to instal and operate a pasteurizing plant are by no means the only obstacles to this reform. Owing to the misinformation and prejudice that are so rife—a position for which some members of our profession are evidently in part to blame—there are many large dairies whose directors are unconvinced of their duty to pasteurize. I now have the misfortune to be supplied in my own household by such a firm. Having hitherto been supplied with pasteurized milk by another dairy, I am compelled, by a new zoning scheme for milk delivery aimed at economy in transport to accept raw milk from the dairy to which my area is allotted. As an advocate of pasteurization for many years I find this an intolerable and almost ludicrous position. If we must be deprived of choice of dairy, then the time has come when we should again demand compulsory pasteurization.—I am, etc.,

LAWRENCE P. GARROD.

Local Application of Promin in Tuberculous Lesions

SIR,—I was interested to read in the article by Prof. W. H. Tytler and Dr. A. D. Lapp (Dec. 26, p. 748) of the treatment of superficial tuberculous lesions by the local application of promin, the success of which raises once more the hope that even the tubercle bacillus may eventually succumb to chemotherapy. In their report the authors state that the trial treatment of cases of pulmonary tuberculosis has been fairly extensive though published results are yet scanty. More detailed reports will be awaited eagerly.

Meanwhile it is interesting to speculate on some possible general applications of a drug having a selective action for the tubercle bacillus. Such a drug might be used with great success on the early case with the minimal lesion and moderate toxaemia; some sort of prophylaxis with regard to contacts might also be possible. The high solubility and rapid absorption of promin, however, together with its effect on the blood cells when used in high concentrations, would appear to preclude its use in this direction at present.

But it is the chronic consumptive with his persistently positive sputum who creates the biggest obstacle to the successful treatment of tuberculosis. Sanatorium can benefit him very little except to isolate him from the community and his environment for a time. Such a patient, although incapacitated, is not always ill; there is little toxaemia, and one might hesitate to flood his system with a drug capable of destroying the bacilli *in situ*, if such were possible. Might it not cause a marked toxaemia from the disintegrating organisms? This is only conjecture, and one must await the result of further trial. Meanwhile there still remains, as the authors assert, the justification for more extensive trial of promin by local application to suitable lesions.—I am, etc.,

Congleton. D. S. HAYES.

Staffing Mass Miniature Radiography Units

SIR,—The battle for mass miniature radiography has been brought to a successful conclusion with this form of examination now established in the three Services, and an early start is anticipated on the civil population this year. But as yet we have no specific details of the exact organization that is proposed for the control and running of the units.

The accurate interpretation of these miniature films is important and frequently difficult. The staffing of the units with adequate, properly trained, and experienced assistants is essential, otherwise the method must rapidly degenerate and fall into disrepute as the result of faulty diagnosis and wrong disposal of the patient. To become expert in interpretation of radiographs of the chest requires many years of wide and varied experience in this field, whether a radiologist or "an expert chest physician" with knowledge of chest radiology. We are told there is now a scarcity of such "experts," and therefore the importance of the careful selection of those responsible for the running of the units cannot be overstressed. It does not follow that because a medical practitioner receives an appointment as a tuberculosis officer he is fully conversant with radiological interpretation of the chest. The reverse is not infrequently the case. Nor does it follow that because someone possesses an *x*-ray plant or holds hospital appointments in radiology he is expert in chest radiology. It might therefore seem that whatever staffing of these units is finally decided upon, more than one opinion on each chest film would be advantageous, and a safeguard to reduce the possibility of error of diagnosis. Perhaps each unit will have attached to its staff one chest physician and one radiologist experienced in chest radiology to form a panel of "expert interpreters," while these units may eventually become distributed throughout the country on a regional basis, with a central administrative panel or committee to which final appeal could be made in cases of extreme difficulty of diagnosis.

As to the claim of the "competent chest physician" who suggests all the work, both clinical and radiological, should be the province of the physician only, this is surely a retrograde step. After all, only some 3 to 5% of the cases are commonly pathological, and consequently a chest physician performing the dual role would be devoting an additional 95% of his time to viewing normal lung fields. Might not his expert services be more profitably employed in his real province—the clinical side of the examination?

In this country the number of examinations achieved per hour, day, or year seems to be modest compared with the claims of Continental workers. The numbers examined by the individual unit, however, largely depend on the number of assistants and the dressing space available to permit patients to pass as a constant stream through the *x*-ray machine; also the inclusion of an electrically controlled camera in preference to the earlier experimental hand-operated camera, and, finally, the use of long strips of film (100 to 200 negatives) instead of the short 36-negative pieces. The most recently published figure by the R.A.F., suggesting a target of 100,000 cases per unit per year, should be speeded up to 300,000 or nearer 500,000 cases a year. At a speed of 100,000 cases a year it would take 80 years for one unit to examine Greater London.

As to the civil organization and the radiologists available, it is my view that radiologists are not fully organized in this country. There is still overlap between the voluntary hospital and E.M.S. radiologists in that much of this work could be fused and one carry out the two duties and some additional *x*-ray work as well. Until radiologists are mobilized more on a national basis this overlap will persist and so the apparent shortage be exaggerated.—I am, etc.,

London, W.1 NORMAN P. HENDERSON.

Intestinal Obstruction

SIR,—The reading of the medical memorandum by Mr. V. C. J. Harris on an unusual case of intestinal obstruction in a child (Dec. 26, p. 754) and the annotation on gastro-intestinal concretions (p. 757) brought to my memory a case upon which I operated a few months ago of a woman, aged 71, who had complained for 6 days of severe abdominal pain centred round the umbilicus with vomiting and constipation of 5 days' duration. Her abdomen was somewhat distended and tender and a diagnosis of obstruction was made. A laparotomy was performed, which revealed the presence of a moderately inflamed and distended small gut with free blood-stained peritoneal fluid and a hard round mass which appeared to be obstructing the terminal ileum. An incision was made over the mass and it was removed and the bowel sutured. She made a good recovery. The mass subsequently proved to consist of congealed faecal matter on a base of fruit skins, and was quite hard. Inquiries after operation showed that some days previously she had partaken of raw Victoria plums, which, she said, had never agreed with her.

This case also called to mind the reports of others very similar (Latchmore, "Stomach-ache," *Lancet*, 1940, **1**, 1153). Perhaps obstruction by a food bolus or bezoar is by no means so uncommon and should be borne in mind in differential diagnoses of obstruction. The legend of the bezoar stones, which was generally credited in olden times, was that they were the crystallized tears of deer. The deer ate snakes, which caused such intense stomach-ache that tears were brought to the animal's eyes, and these subsequently congealed beneath the lid as stones. These fell out and men gathered them up. Cases of poisoning and other noxious diseases were said to have been cured by them, and one was used as a last resort at the death of King Charles II (R. E. M. Coke Harvey, "Medical Bypaths: A Record of Some Peculiar Practices," *Middlesex Hospital Journal,* 1939, **39,** 128). It may possibly be of interest to the academically minded surgeon to consider that what was once a magical stone endowed with life-giving properties is now a cause for surgical intervention and a portent of evil.—I am, etc.,

Aylesbury RALPH H. GARDINER

Treatment of Dysentery at Sea

SIR,—So much has been written about the treatment of dysentery that one hesitates before reporting one's own results. However, treating dysentery on shore with the advice of laboratory findings and treating it at sea are two different propositions. Because of this the experience obtained on this voyage will, we trust, prove useful, not only to others in similar circumstances but also to those who are not in proximity to a laboratory.

The first case was that of the chief steward. He had had diarrhoea for six days and had been "warding it off" with double whiskies with some degree of success till the sixth day, when this ally failed him. During this time he had had very little to eat, and was weak when first seen. Stools were very frequent, the temperature was 99.5° F., and the pulse 105. Ol. ricini 1 oz. was given at once and fluids prescribed, brandy being allowed in small quantities because of the low state of the patient. The following day mist. bismuth. was given four-hourly. At the end of the day his condition was worse, the evening temperature being 101° F. The following day, no sodium sulphate being available, magnesium sulphate was given four-hourly. Food was still withheld, but the bowels continued to act frequently, blood and mucus being passed. This continued for the next twenty-four hours, when the evening temperature was 102° F. The possibility of an amoebic infection was considered, and it was decided to try an injection of emetine hydrochloride 0.03 g. Two to three hours later the patient showed a slight improvement, there being a decrease in the abdominal pains, although blood and mucus were still being passed. A second injection was given the same evening and two more the following day, when the evening temperature was still 101° F. The next day we were able to get ashore and have a microscopical examination of the stool made. No amoebae could be seen, and the appearances were more in favour of a bacillary infection. We were unable to obtain the result of the culture.

Treatment was discussed with the medical specialist at the R.A.F. hospital at Aden. He stated that he had been using sulphapyridine in similar cases with most satisfactory results, using two tablets three times a day for two days. We had not previously heard of this treatment for bacillary dysentery and decided to try it on our patient. The result was almost dramatic, and within twenty-four hours there was a most marked improvement, and at the end of thirty-six hours he was up and commencing his normal duties. Following up this treatment we used sulphapyridine on several other cases which were not clearing up; these were not so severe as the first one. Again the results were most satisfactory.

A number of other patients reported complaining of diarrhoea, sometimes of forty-eight hours' duration and not uncommonly showing blood in the stool. The routine treatment we adopted was as follows: 1 oz. ol. ricini was given at once, and liquids only were allowed—that is, barley water or oatmeal water to which a pinch of ginger had been added. Six hours later two sulphapyridine tablets were given followed by two more in another four hours, after which soup and dry toast were allowed. The following morning two more sulphapyridine tablets were given and light meals allowed. By this time the condition was nearly always under control, but bismuth was given for two days.

We would point out that these results appear to confirm those obtained by the medical specialist at the R.A.F. hospital at Aden, who first drew our attention to the value of sulphapyridine in these cases. Treatment at sea is given under extremely difficult conditions, as one has not the advantage of laboratory findings. Allowing for this we have been so impressed with the results of sulphapyridine treatment following castor oil that we feel this method is well worthy of fuller trial.—We are, etc.,

Flight Lieut., R.A.F.
W. GORDON RICH,
At Sea Major, N.Z.M.C.

Teaching First Aid

SIR,—As one who, like Dr. G. Laurence (Dec. 26, p. 767), has to teach first aid to members of both the Red Cross Society and the St. John Ambulance Brigade I should like to endorse his plea not only for a common textbook but also for a complete revision of the teaching as now published.

The war casualties have taught us, as he states, that the treatment of the patient is more important than that of the lesion, and that for the lesion improvisations are more probable methods of treatment than the set number of bandages and splints as set forth in the textbooks. To give just one example—a compound fractured femur sitting on a chair at the time of his injury was dealt with here by dressing the wound, tying the feet together, and a spot of morphine. He was then carried on the chair, no other method being possible as a stretcher could not get past the debris till the way was clear, when he was removed to hospital on a stretcher, no more splints or bandages being applied. Though very shocked when found he did very well.

The results of dealing with cases like this and of teaching numerous first-aiders have convinced me not only that simpler methods, including more practice in improvisation, should be taught but that the stress which is laid in the textbooks on the bandage and the splint, their positions and number, should be replaced rather by a stress on what the first-aider is seeking to accomplish by their use. This is certainly mentioned in the textbooks, but in their present form the emphasis is all on "one above and below the fracture," etc. This also applies to the teaching on haemorrhage, and has no doubt led to many mistakes. Here the stress, owing to the necessity, which is of the utmost importance, of learning the pressure points, has been on arterial haemorrhage. The types of haemorrhage can be rammed over and over again into a class, but the thrills of a pressure point and, still better, the tourniquet are irresistible; so on it goes, stopping the steady stream, but quite unnecessary and of course dangerous. In big print the textbook should deal with the types of haemorrhage, stressing the need for diagnosis of the type, and a word on the probable frequency of the types might help.—I am, etc.,

Skegness M. BACKWELL.

First Aid for Fractured Spine

SIR,—I have read with much interest the letters on the above subject, and I am also indebted to Mr. Thos. Stowell for very full details of his method of turning cases of this type. As a general practitioner in a busy colliery village (blessed with an excellent first-aid personnel) I would ask the experts, Why is it necessary to turn the patients at all, why not do them up as they lie?

This colliery has its share of accidents, and as the nearest hospital is 30 miles away transport of serious cases calls for fairly efficient first aid. The following is the method of dealing with cases of fracture or suspected fracture of the spine as carried out by the colliery team under Mr. Robt. McCormick. So far no complaint has been received from any patient, and the surgeons have at one time or another been quite complimentary.

Kirkconnel Method

Personnel: 4 first-aiders, whom we will number 1, 2, 3, and 4

Materials: 1 strong rug or blanket; 2 splints to extend from head to feet; 2 splints to extend from armpits to feet; 1 rug to make a pad between the legs; 7 triangular bandages and 1 short splint to pass the bandages.

Bearers 1 and 3 take up position at the sides of the patient, No. 4 is at the head, and No. 2 at the feet. The rug is pleated up from top to bottom and is placed at the patient's head. Nos. 2 and 4 apply extension and counter-extension, while Nos. 1 and 3 pull down under the injured man in the following manner. Placing their inner hand against the patient's side, they grasp the edge of the rug with the outer hand and pull downwards and outwards, so that, besides pulling down, they are also pulling against each other. This prevents the edges from being turned up and thus increasing the friction; in addition it maintains a minimum of thickness between the patient and the ground. The first pull is made to the waist, and by successive pulls the whole rug is drawn down to this hollow, the upper edge remaining at the level of the head. By a similar movement it is pulled into the hollow below the buttock and, in successive stages, to the feet. The rug is now "straightened out" and turned over the patient while bandages are passed as follows: under the neck, armpits, upper chest, lower ribs, hips, above the knees, and under the ankles. The covering rug is again spread out on the floor and the folded pad made with No. 2 rug is placed between the legs: it should reach from the crotch to the feet.

The two short splints are now placed on each side edge of the rug, the top level with the head. They are then rolled inwards in the rug and traction is exerted on them till they come tight up against the patient's body with the part under his back perfectly taut. Bearer No. 1, standing at the head, grasps the rolled-in splints at the level of the shoulders. No. 3 astride over the patient grips opposite the hips and No. 2 grasps the rolled-up rug at the ankles. All lifting carefully together, the patient is slowly raised a couple of inches from the ground, just sufficiently to allow the two long splints to be slipped under the patient on top of the bandages, so as to lie along either side of the spinal column. The patient is carefully eased back to the ground and the short splints are rolled out of the rug and re-rolled in it so that their upper ends are now at the level of the axilla. In tying the bandages, starting at the top, the first and second are tied to each other close to the seams of the jacket and the long ends tied together over the chest in the middle line. The remaining bandages are tied firmly in the middle line, except that at the ankles, which forms a figure-of-eight around the feet.

Loading on to a stretcher is performed by the same lift as was used to pass the long posterior splints. For a long journey the back splints may be padded with rugs folded lengthwise, and the side splints can be padded with tow, etc., if desired. Pads of wool may be placed under the bandages on the chest to prevent friction.

For the prone position a similar procedure may be adopted, the splints being placed either down the back or under the abdomen. Owing to the absence of natural hollows when lying prone, a modified method of rug passing will be called for. A pull of six inches only is made from the head, and then, by a series of 6-inch waves, the rug is passed to the feet. This assures that there is only a small area of folded rug under the patient at any one time. This latter method can also be used for supine patients whose "natural hollows" are not much in evidence.

For fractures in the cervical region the following additional equipment is required—2 bandages, 2 short splints, and 2 large pads. The procedure is the same as for trunk fractures, but the extra bandages are placed under the head and neck. The two pads are used to steady the head, and are supported by the short splints, which, in the final roll-in, are used from the shoulder to the top of the head.

The final result obtained by this method is: (*a*) the patient runs no risk of further damage by being moved unnecessarily; (*b*) he is comfortably encased in an "orange-box" which allows of safe and easy transport; (*c*) he can, on arrival at hospital, be placed, if desired, directly on the *x*-ray table, the back splints can be slipped out, and he can still be safely handled for removal to bed after the desired exposures have been made.

It may be emphasized that the technique is very much easier to carry out than it is to describe in detail. Theoretically it may be all wrong: in practice it yields satisfactory results. I am much indebted to Mr. McCormick for assistance in detailing the various steps in the above description.—I am, etc.,

BOWMAN EDGAR,
Kirkconnel M.O., 4th Battn., Dumfriesshire H.G.

Artificial Respiration

SIR,—In justice to Schafer's memory it should be noted that his method is that of the cylinder and piston. It is unauthorized modifications of it that demand chest elasticity. The Royal Life Saving Society has the original paper for verification.—I am, etc.,

Birmingham W. J. BURNS SELKIRK

SIR,—Surg. Lieut. G. H. Gibbens (Dec. 26, p. 751) has done a good service in reminding the profession of the advantages of Eve's method of artificial respiration. I have always felt that the rationale of the Schafer method as outlined in the St. John organization textbook and the Royal Life Saving Society A.R.P. handbook was unconvincing. They teach that the "piston" action of the diaphragm is the main factor in causing lung ventilation, but as the diaphragm and abdominal musculature are placid and almost toneless in the apparently dead I fail to see why the "viscera resume their former position, the diaphragm descends . . ." when pressure on the loins is released in the inspiratory movement. It may do so in practice on the *living* subject, but conditions are not comparable.

In Eve's method this piston action is ensured by gravity and the attachment of liver and stomach to the diaphragm. It appears to me that Eve's method has a definite theoretical superiority over Schafer's, which would seem to be borne out by practice.—I am, etc.,

Seascale, Cumberland L. GOLDMAN.

Absorption of Iron

SIR,—The rate of hydrolysis of a number of organic iron salts to colloidal ferric hydroxide and to particles of ferric hydroxide was observed in an alkaline medium (sea-water, *p*H 8.2). Of these the ascorbates were least rapidly hydrolysed and precipitated.[1] The solubility of ionic iron in alkaline media is extremely low, no more than 4×10^{-10} mg. Fe per litre of Fe^{++}, Fe^{+++}, $FeOH^{++}$ at *p*H 8 when equilibrium has been attained,[2] although the concentration of dissolved oxygen may have reached a very low value.[3] It is limited by the insolubility of ferric hydroxide.

From these observations it appeared that absorption of iron in the intestine of mammals might be increased by the presence of ascorbate in the gut contents. This should allow a longer period during which diffusible iron remains in solution after the contents become alkaline. With this possibility in view a patient of one of us, with severe secondary anaemia, who had been treated with large doses of iron and liver for one year (raising the Hb level from 39 to 60% and red cell count from 3,710,000 to 4,590,000 without clinical improvement) was treated with 15 gr. ferri ammon. cit. together with 50 mg. ascorbic acid thrice daily. After 2 months there was very marked clinical improvement and the Hb level had risen to 80%.

It would be of interest to hear of any similar results which support this single observation. The tentative hypothesis which may have led to this encouraging improvement obtains some support from observations that increased alkalinity of the diet has been observed to depress iron absorption and the therapeutic effect of iron salts, while acidity is favourable.[4] It neglects the possibility that ascorbic acid may affect iron transport within the body or haemoglobin formation: cases are recorded where dosage with ferrous sulphate raises the haemoglobin content and lowers the ascorbic acid content of the blood,[4] and intravenous injection of ferric ascorbate is reported to cause a haemoglobin formation in excess of the quantity of iron injected.[4]

Our thanks are due to Dr. Barbara Thomas of the Prince of Wales's Hospital, Plymouth, for permission to publish this case, and to Dr. E. Wordley for blood counts and haemoglobin estimations.—We are, etc.,

H. W. THOMAS.
Plymstock H. W. HARVEY.

X-ray Department at Health Centre

SIR,—I do not think it will be clear to your readers from the letter of Dr. J. V. Sparks (Jan. 2, p. 23) what he requires in these health centres. Does he really think it justifiable to put a large *x*-ray unit in every one of the many centres? Does he expect every centre to have the services of an expert radiologist, since he expects the early diagnosis to be made there and deprecates the transfer of the patients to another centre for further investigation? If he thinks the provision of "apparatus of adequate 'power' to be the only requirement, why should he expect the medical practitioner to understand the equipment and interpretation of the radiographs? He would not expect him to be an expert microscopist, biochemist, cardiologist, etc., and he would not expect every such clinic to be provided with the most expensive microscope and biological equipment, though the cost and upkeep of these are small compared to the *x*-ray unit (even the 30 mA unit, the use of which he undervalues, would cost upwards of £500).

---

[1] Harvey, H. W. (1937). *J. mar. biol. Ass.*, **22**, 205.
[2] Cooper, L. H. N. (1937). *Proc. roy. Soc.*, B, **124**, 299.
[3] —— (1937). *J. mar. biol. Ass.*, **22**, 167.
[4] Schultze, M. (1940). *Physiol. Rev.*, **20**, 37.
[5] Farmer, C., Abt, A., and Aron, H. (1940). *Proc. Soc. exp. Biol.*, N.Y., **44**, 495.

Surely patients needing these investigations could be referred to the larger clinics possessing experienced staff and adequate equipment. The words of J. E. Goldthwait (*J. Bone Jt. Surg.*, 1933, April, p. 279) are pertinent here: "In many of our large clinics it would be far better to have the 'chief' remain in the out-patient department and let the junior staff carry out the operation work. The skill required for this operative work is much less than that required for diagnosis."

Dr. Sparks's comments on mass radiography are even less convincing. The provision of the 25 mass radiographic units is admittedly for experiment and not a solid contribution to preventive medicine, since to mass-radiograph the population you need at least 500 such units. The only additional evidence these experimental sets will yield, providing they are used by competent workers and subject to criticism, is the relative efficiency of the medical examinations in different areas by different doctors. The revelation of extensive progressing tuberculous disease in a patient should not be regarded as a triumph for mass radiography but rather a slur on the medical examination which missed it. The Ministry maintains that "mass radiography will not be the basis of diagnosis but will be used to sift abnormal cases from the normal in apparently healthy persons." The abnormal will be further examined by other means of diagnosis. Is it reasonable to sift as long as they are apparently healthy? I know from experience that they may and do remain apparently healthy for 20 or more years in spite of certain *x*-ray appearances. Obviously, as it is to be used as the sieve to separate the abnormal from the normal it will be the basis of diagnosis, but, as I have shown, it is a defective sieve which will miss the early case. How will mass radiography help in the detection of such cases as the contacts we see which may be radiographically negative at the first examination but showing extensive tuberculosis after an interval of 3 to 6 months?

The selected inconspicuous lesions may or may not be of clinical significance; they may look suspicious and remain so for 20 or more years, but not until they are associated with clinical signs are they of any significance and should not be allowed to spoil the life of the patient.

Radiology should hold a very high place in diagnosis, but it will deservedly lose it if it is used as a quick substitute for clinical methods.

To carry out mass radiography of the population a large army of full-time experts would be necessary. Are the men who have advised this method of investigation prepared to do the work?—I am, etc.,

Birmingham. JAMES F. BRAILSFORD.

SIR,—The recent article (*Supplement*, Nov. 7, p. 57) and letter (Jan. 2, p. 23) by Dr. J. V. Sparks on the subject of the small *x*-ray set proposed to be installed in the suggested new health centres should call out the support of all radiologists lest wartime conditions perpetuate themselves afterwards. There is a very general impression among non-radiologists that the size and power of an *x*-ray set are somehow related to the number of patients to be examined or to the importance of the hospital. It cannot be too strongly insisted that this is a fundamental error.

The power output necessary in an *x*-ray set is a function only of the permissible length of exposure. Small sets are, therefore, sufficient for limb examinations or to give a rough idea of gross lesions of lungs, etc., in the wards. An adequate chest film requires an exposure time of not more than 0.12 sec., and much less in children, to prevent blurring from the movement of the lung vessels alone, and at least a 200 mA output is necessary for this. Many small sets even have time errors as great. Presumably a good deal of chest examination would be called for at the health centres.

A 200 mA output takes one first to the region of that much-debated horror, the two-valve set. In the first place, this output would be their maximum rating, something which many sets of whatever type never attain. Secondly, two-valve sets are inherently very tricky to use with the Bucky diaphragm if film lining is to be prevented. Thirdly, a two-valve generator differs from a four-valve in price by very little more than the cost of the two extra valves, about £100, or an increase of about 1/6th or 1/7th. A four-valve set for this relatively small extra cost has double the output of a two-valve, making really good chest films possible, a thing absolutely necessary for the diagnosis of early disease. A four-valve set is also very much easier to use with the Bucky, and the saving in film wastage would more than compensate for the extra £100 of first cost within the set's lifetime.

Four-valve sets are not by a long way the last word in equipment, but from the above reasons one can see why they have been adopted all over the world as the minimum necessary for routine work. It is of no use protesting that they cannot be afforded. If they cannot, then the proposal to put any *x*-ray set in the health centres should be dropped as a waste of money, an expensive pretence. I would suggest that the minimum equipment necessary for any place where more than limb radiography is to be undertaken would be a four-valve generator, a rotating anode tube—without which modern high-speed, fine-detail radiography cannot be attempted—and a tilting couch with Bucky and barium equipment. There are now at least three rotating anode tubes capable of continuous screening as well as radiography. A chest stand would also be required. If this is too big, let us face the facts squarely and put in no *x*-ray plant but attack the problem in some other way.—I am, etc.,

Hairmyres Hospital, East Kilbride D. J. HURRELL

Service Cases of Venereal Disease on Demobilization

SIR,—Dr. Philip Silver's suggestion (Dec. 26, p. 766) that all members of the Services and the Civil Defence organizations should undergo a Wassermann and a Kahn test before discharge to civil life is an excellent one. May I suggest that as an immediate measure to prevent an increased incidence of congenital syphilis these tests should be done on all women in the early months of pregnancy. Dr. Violet Russell put forward a most convincing case for a routine Wassermann or Kahn test in a paper, "Venereal Disease and the Pregnant Woman," read at the Health Congress of the Royal Sanitary Institute in July, 1935. There are, unfortunately, still far too many ante-natal clinics not yet in line with those of Kensington in undertaking this increasingly urgent routine investigation.—I am, etc.,

London, W.1. D. KATHLEEN BROWN.

Charting the Pulse

SIR,—Your annotation on charting the pulse (Dec. 19, p. 728) gives publicity to a clinical method which is too little practised. On returning to India after 6¼ years' military service in 1921, I was sufficiently impressed by the lack of appreciation of pulse values to institute pulse–temperature charts (with accent on the pulse) in the district to which I was posted and carried it to subsequent stations on transfer. As C.M.O., Delhi, I introduced it into the enclave of the Government of India, and later, when Inspector-General, it was spread throughout the Punjab. Its particular value in India was to demonstrate the pulse–temperature ratio in the typhoid group. My charts place a pulse rate of 70 against the temperature of 98° F., rising by decades with each degree of temperature, with a note that pulses were to be charted in red ink and temperatures in black.

I must confess that my subordinates showed no enthusiasm and only a polite interest in my "foible" and would not be surprised to learn that it had fallen into disuse. *Sic transit.*—I am, etc.,

C. H. REINHOLD,
Whitchurch. Col., I.M.S. (ret.)

R.M.B.F. Christmas Gifts

SIR,—I cannot convey more adequately my thanks to your readers for their most generous response to my Christmas appeal than by quoting the letter of a beneficiary, a doctor's widow aged 88, who writes:

> "Owing to being very feeble and at times not able to hold my pen, it is not possible to write, but I do want to thank you and my good medical friends who sent me the Christmas gift so acceptable. I am most grateful, for I need much I cannot obtain. Again I thank all to whom I have been indebted for so many years, but the time is getting short. I am very feeble and cannot help myself, also memory and deafness very trying. Yours gratefully."

It is of the greatest satisfaction to me to know that, thanks to your help and the generosity of many, we have not failed to send a Christmas gift to all our regular beneficiaries.—I am, etc.,

1, Balliol House, Manorfields, THOS BARLOW,
Putney, S.W.15 President, Royal Medical Benevolent Fund

Obituary

WILLIAM MacLENNAN, M.B.

G. M. writes:

A full appreciation of the life and work of Dr. William MacLennan has, I hope, been presented by one of his immediate colleagues, and my desire is to express a brief but affectionate tribute to the memory of one from whom I and many others of his pupils and housemen have received our infant nurture and inspiration in medicine. Dr. MacLennan came to hospital and consulting work with a wide experience of general practice, a natural gift for teaching, the zeal and enthusiasm of an evangelist, and the gentleness, understanding, and sympathy of the Great Physician, to whom his life was dedicated in the service of his fellow men. Impairment of his vocal functions led to an early curtailment of his teaching activities, but retirement from hospital only led to an increasing demand for his services as a consultant, while in later years even a serious crippling of his cardiac capacity, which immediately threatened his life, failed to arrest his zest for work. Those of us who had the privilege of visiting him in retirement in his lovely country home at Doune and there enjoying anew the inspiring atmosphere of his dynamic and lovable personality wish to take a fond farewell of a beloved physician.

In the course of another appreciation J. S. C. writes: His *Manual of Diseases of the Stomach for Practitioners and Students* bears the imprint of his vital clinical acumen, and in it he gives in full measure from his deep knowledge of diagnosis, prognosis, and therapeutics. He wrote in the same manner as that in which he worked at the bedside—in close logical pursuit of his objective. When MacLennan was examining at the Finals in Glasgow or Aberdeen the candidate felt the penetrating rays of a keen adjudicator, giving rise to tension but never to emotional shock. In the last war he took his heavy load of Army service in his stride, and then illness halted him awhile. Although sad at having thus to leave his wards and his students, he marched on again with his other work until the eve of Christmas, 1942. To our mortal eyes our ranks are thinned, but that company of great physicians marching ahead is reinforced.

News has just been received of the death at Newcastle, N.S.W., on Aug. 3 last, of Dr. ROBERT USHER RUSSELL. He qualified L.R.C.S.I. in 1883 and L.R.C.P.Ed. in 1886, and travelled extensively before settling in Australia. In 1890 he was appointed junior, and later became senior, medical officer at Parramatta Mental Hospital, where he remained until 1896, when he became medical superintendent of the Coast Hospital (now Prince Henry Hospital), Sydney. Two years later he was appointed medical superintendent of the Mental Hospital, Newcastle, a post which he held until he retired in 1922. For a number of years during this time he acted as Port Health Officer to Newcastle. When mental hospitals were opened at Stockton and Morrisset he was elected to visit them, and was mainly responsible for their establishment. He took an active part in sport, particularly cricket and shooting. He was a captain in the A.A.M.C. until 1919. When he retired he settled in Newcastle, N.S.W. His long career was one of unceasing public service, and he was well known for his readiness to help those afflicted by mental ill-health.

We regret to announce the death on Nov. 1 at Bath at the age of 43 of Mr. HENRY MEREDITH MARTIN, born at Colooney, Co. Sligo. He received his medical education at Trinity College, Dublin, taking his M.B., B.Ch. in 1923. He took an active part in the athletic life of the university, especially as a sprinter capable of very fast time in the 100 yards. After qualifying he became resident medical officer at the Gloucester Mental Hospital, and in December, 1924, joined the Naval Medical Service, retiring in 1931 with the rank of lieut.-commander. He saw service in many parts of the world, and his knowledge of athletic training was instrumental in enabling one of his ships to win a Fleet regatta, although boat pulling was not one of his own accomplishments. After some postgraduate study he was elected F.R.C.S.Ed. in 1932. He then became senior casualty officer and house-surgeon at Leicester Royal Infirmary, an appointment which gave opportunity to his surgical talent. After a further year and a half as senior house-surgeon and resident surgical officer at the Royal United Hospital, Bath, he realized an often-expressed wish and spent six months on the Continent studying surgical thought and methods. On his return he held further resident posts, including one at All Saints' Hospital in order to study genito-urinary surgery. His whole career had but one object—the study of surgery—so that when he started as a consultant surgeon in Bath in 1937 his services were soon in demand. In 1938 he was appointed to the honorary staff of the Royal United Hospital as hon. surgical registrar, a post he filled with distinction and energy. After starting practice at Bath he added to his academic achievements by taking the M.Ch.Dublin in 1937 and being elected a Fellow of the Royal College of Surgeons of England in 1939. Harry Martin's death (writes a colleague) occurred after a short illness, during which his calm courage amazed his closest friends; he was still a scientific observer even when he himself was the patient. As a surgeon he was an accomplished operator whose technique was as artistic as it was careful, and no detail was too small for attention. His patients gave him their confidence and gratitude, and to his colleagues he gave advice based on sound judgment, he was possessed of those two great assets of a surgeon—humility and courage. His death leaves a gap in the ranks of the younger surgeons who have the progress of surgery at heart. We have lost a delightful friend, and his hospital a loyal and enthusiastic member of its staff. He married in 1939 Phyllis, daughter of Dr. J. W. Fordham of Leicester, to whom our sympathy goes out in her irreparable loss.

We regret to announce that Dr. JAMES BUCHANAN of Watford died on Dec. 17 at Omagh, Co. Tyrone, in his 79th year. He studied medicine at Belfast and at University College, London, and graduated M.B., M.S. of the old Royal University of Ireland in 1888, after winning scholarships in anatomy and physiology at Queen's College, Belfast. Dr. Buchanan had been assistant school medical officer under the Herts County Council and medical officer to the Watford Infirmary; he was also for some years M.O.H. at Old Calabar, West Africa. He joined the B.M.A. as long ago as 1889 and held office as chairman to the Watford Division in 1935-6.

We regret to announce the death, suddenly, on Dec. 23, 1942, of Dr. C. E. POTTER of Derby. Although he had been in indifferent health for several years he had continued to work, and the end came unexpectedly. Born in Glasgow in 1872, Charles Edward Potter was educated at Bradford Grammar School and at Oliver's Mount, Scarborough. After leaving school he was a "pupil-learner" with a doctor near Durham, and there, at the age of 18, he was first introduced to midwifery when he was called into a house he was passing to assist at a birth. He entered Edinburgh University in 1890, graduating M.B., C.M. in 1894. He studied obstetrics in Dublin, and was for a short time at the Seamen's Hospital, Greenwich. In 1896 he went to Derbyshire as assistant to Dr. Harvey in Wirksworth, and later began general practice in the country district of Parwich, near Ashbourne, where he was also medical officer of health. In 1901 he obtained the Edinburgh M.D., and the following year took over the practice of his brother-in-law in Derby, which he carried on for over 40 years. During most of his professional life Dr. Potter was honorary obstetric physician to the Nightingale Maternity Home, to which he also devoted much time as a member of the board of management. He was an active supporter of the B.M.A., being chairman of the Derby Division in 1925; he was representative on the Maternity and Child Welfare Committee in 1923, and a member of the local executive committee for more than 20 years. That he had the confidence of his colleagues is shown by the fact that he sat on the local emergency committee in the last war and was a member of the Local Medical War Committee at his death. He did not seek office, although he was much valued for his wisdom and common sense. He was secretary to the Derby Medical Society for five years, was a regular attender, and had a successful year of office when his turn came round to be president. He was an active member, one-time secretary, of the Local Panel Committee. He leaves a gap in the local profession which it will be difficult to fill.

We announce with regret the death on Dec. 24 of Lady Cheatle, wife of Sir G. Lenthal Cheatle. She was President of the Ladies' Guild of the Royal Medical Benevolent Fund from March, 1930, to March, 1940. Lady Cheatle combined in an extraordinary degree a very warm and sympathetic nature with a practical and clear-sighted outlook on life. Her advice, often sought and never in vain, was invaluable on any difficult problem. The work of helping the destitute widows and children of medical men was always in the forefront of her life, and she never lost sight of its human element. She took the sorrows of others much to heart, and a beneficiary was to her an individual, never a "case." Her charming, gracious personality and her many little acts of kindness will not easily be forgotten.

We regret to announce the death, at the age of 88, of Dr. FRANK JAMES ALLEN at Letchworth on Dec. 28. He was born at Shepton Mallet on April 17, 1854, and was educated at Taunton School and St. John's College, Cambridge, of which college he was a Fellow, graduating B.A. (being placed in the First Class of the Natural Sciences Tripos) in 1878. He proceeded M.A. in 1882 and in the same year took the M.R.C.S. In 1883 he obtained the L.R.C.P. and two years later the M.B., proceeding M.D. in 1895. From 1887 to 1899 he was professor of physiology at Mason University College, Birmingham. He returned to Cambridge in 1902 and devoted himself to antiquarian and archaeological pursuits, being honorary secretary of the Cambridge Antiquarian Society from 1913 to 1930. In 1932 his book *The Great Church Towers of England* was published by the Cambridge University Press. It was the lifework of his leisure hours and was illustrated almost entirely by his own photographs. He was also deeply interested in music and wrote and published songs, nursery rhymes, and hymn tunes. He returned to Shepton Mallet in 1931 and was active in the Somerset Archaeological Society, particularly in connexion with church architecture. He was recently described by the Bishop of Bath and Wells as "the greatest living authority on church towers." He retired to Letchworth in 1940. Dr. Allen had been a member of the B.M.A. since 1887.

We regret to announce the death at sea by enemy action last autumn of Dr. GEOFFREY CHARLES PURSLOW, son of the late Lieut. George Purslow, who was killed in action in October, 1918, and of Mrs. Mabel Gwynne of Leek, Staffs. He was born on Jan. 19, 1916, and was educated at the University of Birmingham, graduating M.B., Ch.B. in 1940, also taking the M.R.C.S., L.R.C.P. in the following year. After qualifying he was employed as ship surgeon with various steamship companies, and it was while on a voyage in this capacity that he lost his life, his ship being torpedoed on or about Sept. 17. He was a member of the B M.A.

The death took place recently in Melbourne of Dr. GREGORY SPROTT, for many years medical officer of health of Hobart, Tasmania. Dr. Sprott was born in Scotland 80 years ago, and received his medical training at Glasgow, where he qualified in 1885, took the D.P.H. in 1888, and the M.D. in 1894. For a time he practised in the North of England, and then, going out to Tasmania, became part-time medical officer of health for Hobart from 1896 until 1903, and again from 1907 to 1923, and for the following 10 years he served the city in a full-time capacity. He was a man of great reforming zeal, and it was very largely owing to his efforts that an underground system of sewerage was provided for Hobart. He pressed forward the scheme in the face of much criticism, and his administration in this and other respects was greatly to the advantage of the city. It was said of him by one of the city's officers that just as Augustus found Rome brick and left it marble, so Dr. Sprott found Hobart "a stinking cesspit" and left it a clean and healthy city. He also took an active missionary part in urging upon Tasmania the need for vaccination, and through his efforts a Health Act was passed, the most important section in which requires the appointment of a chief health officer who must hold not only a medical degree but the D.P.H. He was mainly responsible for the establishment of the Vaucluse Infectious Diseases Hospital, of which he was medical superintendent, and for many years he was honorary surgeon to the Hobart General Hospital and the Queen Alexandra Hospital. He showed great interest in the work of the St. John Ambulance Association and organized the excellent ambulance service in Southern Tasmania. Dr. Sprott was well known in this country as one of the oversea representatives at the Annual Meetings in 1912, 1920, 1926, and 1934. He was a member of the Central Council and of the Dominions Committee in 1920-1. He was an active member of the Federal Council of the British Medical Association in Australia, a director of the Australian Medical Publishing Company, and a leading spirit in successive Australasian Medical Congresses.

The death of Dr LEWES NICHOLAS GIBBES of Church Street, Kensington, where he had practised for more than forty years, removes perhaps the doyen of the general practitioners of that locality. After study at the medical school of St. George's Hospital, he qualified M.R C.S., L.R.C.P. in 1895. He had been surgeon to the Crippled Boys Home, long established at Wrights Lane, Kensington, and dermatologist to the Princess Louise Hospital for Children in North Kensington. He had formerly acted in temporary capacities at the Golden Square Throat Hospital and at St. George's Hospital; he had also held an appointment as anaesthetist to the King George Hospital. From this record it follows that he was a general practitioner in the real sense of the term, adept in many branches of the medical art.

Medico-Legal

MISUSE OF MEDICAL TITLE

The magistrates of North Shields recently convicted Charles Bernard Clark on charges of unlawfully, wilfully, and falsely using the descriptions doctor of medicine, bachelor of science, and specialist in incurable diseases, thereby implying that he was registered under the Medical Act, 1858. Clark pleaded guilty, and another charge of describing himself as a pathologist was dropped. Evidence was given that he had put up a board at a house in North Shields, displaying his name together with these descriptions and his consulting hours. This board actually deceived a number of persons and made them believe that he was a registered medical practitioner. A married couple who attended him concluded from his condemnation of medical practitioners and hospitals that he was not registered, and consulted their own doctor. Clark sent in a bill, on a form containing the titles which appeared on the board, for a substantial sum. The matter was reported to the London and Counties Medical Protection Society, who prosecuted. Clark was also shown to have been sentenced at Liverpool some years earlier to three years' imprisonment for false pretences. A police sergeant said that no later complaint had been made about him to the police, and some of his treatment had apparently given excellent results. His solicitor said that he had been born in Jamaica and had obtained a degree of B.Sc. at the Cornwall College there. He had been in England for seven years and had acquired some medical knowledge as a private in the R.A.M.C. He had believed mistakenly that he was entitled to practise, and had applied to the Central Medical War Committee of the B.M.A. From a letter written by the Committee he had wrongly understood that he could use the word "pathologist" without being registered. He undertook not to use the titles again. The court fined him £15 on each charge and ordered him to pay 8 guineas towards the legal costs and the expenses of bringing a police witness from Liverpool.

Universities and Colleges

UNIVERSITY OF LONDON

Owing to the date on which Easter falls this year the M.B., B.S. examination will start on Tuesday, April 27, instead of on Monday, April 19.

By a printer's error the name of B. P Webber was printed as B. P Webster in the University of Cambridge Final M.B. (Part I) pass list published in this column on Jan 2 (p. 27).

REHABILITATION IN SCOTLAND

A year ago we announced (Jan. 31, 1942, p. 161) that the Department of Health for Scotland had decided to extend its scheme whereby civilian patients were admitted to emergency hospitals, thus helping to reduce the numbers on the waiting lists of voluntary hospitals. At a Press conference recently Dr. Andrew Davidson, C M.O of the Department, gave figures showing how successful this scheme had been. Some 10,000 patients, he said—8,000 in the last year—had been taken off the waiting lists of voluntary hospitals in Scotland Medical and surgical cases alike had been admitted, but not chronic cases, as the beds had to be readily available, should the need arise, for war casualties. Most of the voluntary hospitals had co-operated, but a few, surprisingly, did not support the scheme The Department made no charge to the patients but received from the voluntary hospital a fixed sum for each person admitted. Dr Davidson also referred to the success of the Clyde Basin experiment, under which treatment is provided free for industrial workers suffering strain, and men invalided out of the Services are restored to working capacity and to their old jobs in the shortest possible time Some 1,600 industrial workers have received treatment since the scheme started and they are now being dealt with at the rate of 100 a week. Since Dr Davidson's conference, when he indicated that there was a proposal to open "fitness centres," the Department of Health has announced that Gleneagles Hotel, which was taken over at the outbreak of war as an emergency hospital, is to be a special rehabilitation or fitness centre for Scottish miners, the first of whom are expected to arrive about Jan. 11. It will accommodate about 200 patients, and has facilities for physiotherapy, occupational therapy, remedial exercises, and physical instruction, as well as entertainment and welfare activities. No charge is to be made for treatment, and the Miners Welfare Commission will pay the patient's travelling expenses. Treatment will last about six weeks, and will be available for miners with disabilities following injuries, for those convalescing after illness, and men suffering from rheumatic conditions.

Medical News

A whole-day conference of the Nutrition Society will be held at the London School of Hygiene, Keppel Street, London, W.C.1, on Saturday, Feb. 6, beginning at 11 a.m., to discuss "Nutrition in Pregnancy." Papers will be read by Mr. Aleck Bourne (Foetal Development), Dr. J. Hammond (Physiological Factors Influencing Birth-weight), Sir Joseph Barcroft (Nutritional Functions of the Placenta), Prof. A. St. G. Huggett and Dr. Margaret Balfour (Diet of the Pregnant Woman), Mr. R. M. Titmuss (Stillbirth and Neo-natal Mortality). The chair will be taken in the morning by Dr. F. H. A. Marshall, and in the afternoon by Brigadier F. A. E. Crew. A subsequent meeting will be held on "Nutrition in Infancy." Further details of the Nutrition Society can be had from the Hon. Sec., Dr. Leslie Harris, Nutritional Laboratory, Milton Road, Cambridge.

"Space and Time in Modern Physics" will be the subject of a lecture by Prof. H. Dingle (Professor of Natural Philosophy at the Imperial College of Science) to be delivered at the British Institute of Philosophy, University Hall, 14, Gordon Square, London, W.C.1, on Friday, Jan. 22, at 4 p.m.

A meeting of the Middlesex County Medical Society will be held at the Central Middlesex County Hospital, Acton Lane, N.W., on Thursday, Jan. 21, at 3 p.m., when Mr. T. G. Illtyd James will speak on "Methods in the Diagnosis of Cerebral Tumours" and Dr. J. Sakula will discuss "A Recent Outbreak of Gastro-enteritis in the Newborn." Visitors, especially members of the American and Canadian Forces at present in this country, will be welcome.

A course of lectures on Social Medicine and Public Health, arranged by the Socialist Medical Association, will be given at the Conway Hall, Red Lion Square, W.C.1, on successive Thursdays at 5.30 p.m., as follows: Jan. 21, Environmental Factors in Disease, Mr. F. Le Gros Clark; Jan. 28, Mother and Child, Mr. Aleck Bourne; Feb. 4, Statistics of Occupational Mortality, Prof. J. B. S Haldane; Feb. 11, Health of the Industrial Worker, Dr. T. O. Garland; Feb. 15, Social and Economic Aspects of Tb., Dr. Brian Thompson; Feb. 25, V.D. as a Social Problem, Dr. Joan Malleson; and March 4, Social Insurance, Prof. Hermann Levy. Tickets, 1s. for each lecture or 5s. for the series, may be obtained from Dr. L. T. Hilliard, Fountain Hospital, S.W.17.

The clinical teaching of medical students is referred to in the latest report of the Birmingham United Hospital. The city authorities were asked whether, in the event of Queen Elizabeth Hospital being seriously damaged, students might continue jointly their work at one or more of the municipal hospitals. The reply was that arrangements could be approved for the continuance at municipal hospitals of medical students, but not for the attendance of their clinical professors, teachers, and tutors. Meanwhile a generous offer by the Wolverhampton Royal Hospital of full co-operation and accommodation for students and teachers has been gratefully accepted.

It is 50 years since the Glasgow Royal Infirmary School for Nurses was opened, and to mark the occasion and to commemorate the work of Sir William Macewen and Mrs. Strong in connexion with it, one of the managers of the hospital has presented two medals to be competed for annually: one, the Macewen medal, to be awarded to the best surgical nurse, and the other, the Mrs. Strong medal, to the best medical nurse. Mrs. Strong, now in her nineties, was a pupil of Florence Nightingale.

The range of British Standards is so varied and the number of war issues so large that no printed list can be up to date, but the latest information about new and revised standards, of which there are at present over 1,000, can be obtained from the B.S.I. Library at 28, Victoria Street, Westminster. These standards may be studied in the library between 10 a.m. and 5 p.m., Monday to Friday, and at other times by appointment.

Under a new Order (S.R. & O., 1942, No. 2668), which came into force on Jan. 5, quinine and its salts may not be prescribed except as anti-malarial drugs, although quinidine may still be prescribed for cardiac arrhythmia. No person may "acquire, treat, use or consume" cinchona, cinchona products, or synthetic substitutes except under licence from the Ministry of Supply. Stocks equivalent to more than 16 oz. of quinine must be declared to the Director of Medical Supplies, Portland House, Tothill Street, London, S.W.1.

The Service Libraries and Books Fund are appealing for more books and magazines for the Forces. Although the number already distributed since the beginning of the war—some 14,000,000—may seem large, the life of reading matter with the Forces is very short. The need, therefore, is for continuous help from the public, not just sporadic donations of books and magazines. They can be handed in at a post office and need not be wrapped or addressed.

The curator of the laboratory of the Royal College of Physicians of Edinburgh, Dr. Fergus Hewat, reports that the research and routine services were fully maintained during 1941. In the research department cancer diagnosis has long been the special task of the laboratory. Other directions of activity are postgraduate laboratory instruction and direct and visiting consultation with practitioner and patient. It is mentioned that most of the post-war planning for medical laboratories makes reference to centralization of technical examination, of which the laboratory at Edinburgh has been, perhaps, a pioneer example in the British Isles. Complete examinations comprised under histology, haematology, bacteriology, and biochemistry are carried out under unified direction.

At the request of the Czechoslovak Government arrangements have been made for a unit of 60 beds for Service and civilian patients of Czechoslovak nationality to be established at Hammersmith Hospital (L.C.C.). The medical and clerical staff required in addition to the normal establishment will be provided and paid for by the Czechoslovak authorities, but all nursing and domestic staff will be engaged and paid by the L.C.C. The new unit will be regarded as an integral part of the whole hospital, and the medical superintendent will be in general administrative control.

The National Science Fund of the National Academy of Sciences announces two prizes of $2,000 each, to be known as the Charles L. Mayer Awards, to be given for outstanding contributions published in 1942 and 1943 respectively "to our knowledge of factors affecting the growth of animal cells, with particular reference to human cancer." To assist the fund in the administration of the awards a special advisory committee has been appointed, and this committee will welcome suggestions on outstanding contributions published in 1942. The address of the National Science Fund is 515, Madison Avenue, New York City.

Since the beginning of the war £100,000 has been raised—almost half of it during the year 1942—for hospital and ancillary services under the auspices of the Bristol Hospitals Fund. The Fund was inaugurated in July, 1939, and represents the co-ordination and extension of contributory schemes which had been running in connexion with the Bristol hospitals. It has been made the central contributory scheme of the six voluntary hospitals of Bristol—the Royal Infirmary, the General Hospital, the Royal Hospital for Sick Children and Women, the Eye Hospital, the Homoeopathic Hospital, and the Cossham Memorial Hospital.

A fund has been started in this country for a memorial hospital in Abyssinia to Princess Tsahai, who took up nursing while an exile here and died as she was about to put her training into practice in her native country. It is proposed to have medical and nursing staff attached to the hospital, to prepare Ethiopians to work in their own institutions, also a research unit, a library, and a service to treat out-patients in the villages. Donations to the Fund should be sent to Miss Isabel Fry, Church Farm, Buckland, near Aylesbury, Bucks.

The Central Council for Health Education, Tavistock House, Tavistock Place, London, W.C.1, appeals to medical practitioners with a flair for teaching to undertake to give occasional lectures in their own localities on health subjects, including venereal diseases An adequate allowance will be made to meet all expenses. The Central Council for Health Education has been made responsible by the Ministry of Health for the central provision of health education throughout England and Wales, and it is much hoped that public-spirited doctors will help it in its important task of instructing the public on matters of health and hygiene.

The following medical promotions in and appointments to the Venerable Order of the Hospital of St. John of Jerusalem have been announced: as Knight, Dr. W. H. Kauntze, C.M.G., M.B.E.; as Commander (Brother), Col. J L. Hamilton, *M.C.*, T.D.; as Officers (Brothers), Dr. A. Johnston, Col. G C. Kenning, R.C.A.M.C., Col J. B. Hance, C.I.E., O.B.E., I.M.S., Capt. J Pirie, Dr. J. Lamberton, Lieut.-Col. C. W. Eames, D.S.O., T.D., Dr. E. H. Shaw, Major F. T. Deatker, O.B.E., I.M.S., Dr. E. S. Bowes, Brig. H. E. Shortt, C.I.E., O.B.E., I.M.S, Col. W. C. Spackman, I.M.S, Col. J. P. Huban, O.B.E., I.M.S., Lieut.-Col. J. C. Pyper, O.B.E., I.M.S.; as Associate Officers (Brothers), Dr. P. Ellman, Dr. P. C. Roy; as Officer (Sister), Dr. Frances C. B. McKay; as Serving Brothers, Dr. J. C. D. Carothers, Dr. W. L. Ingham, Dr. P. L. Regan, Dr. D. Grieve, Dr. A. M. Pollock, Dr. R. G. Tame, Dr. C. H. Smith, Dr. P. S. Martin, *M.C.*, Dr. J. T. Whitley, Dr. J. Ewing, Dr. W. D. Neill, Dr. G. M. Stoker, Lieut.-Col. S Hunt, Dr. W. A. Ogilvy, Capt. M. A. Watson, R.A.M.C., Dr. J. Brown, Mr. E. Pearson, Col. J. E. Rusby, *M.C.*, Dr. J. A. E. M. Hadley, Dr. M. C. Lavin, Capt. P. M. Gettleson, R.A.M.C., Dr. J. Manuel, Dr. F. T. Simpson, *M.C.*, Dr. E. Haworth; as Associate Serving Brothers, Dr. M. N. Oster, Dr. B Narayana, Dr. J. M. Rakshit, M.B.E., Dr. S. C. Datta, Dr. P. N. Kapur, Dr. R. C. Mahajan, Dr. M. M-ud-D. Chughtai; as Serving Sisters, Dr. May Rutledge, Dr. Margaret J. Trotter, Dr Harriet R. L. Reid.

The Medical Society of Pernambuco, Brazil, has recently celebrated the centenary of its foundation.

Dr. Bernard Moiser's years of work for the relief of lepers in Rhodesia have been recognized by the award of the O.B.E. in the New Year Honours list. In his official capacity to the Government of Southern Rhodesia Dr. Moiser supervises the leper settlement at Morgenster in the Victoria District, which, under his expert direction, grows its own crops and keeps its own cattle. He was Assistant Director of Medical Services in Nigeria before he was appointed to Rhodesia, and is an old student of Guy's and University College Hospitals.

There is only one woman doctor of medicine in Peru, Dr. Mercedes Cisneros, who practises in Lima, whereas in Chile there is an Asociación Médica Feminina with 300 members.

Large quantities of serum, including anti-gas-gangrene and dysentery serums, will shortly be sent by air to Russia from the South African Institute for Medical Research in Johannesburg.

The Minister of Health has appointed Col. Frank Medlicott to be his Parliamentary Private Secretary in succession to Mr. N. A. Beechman.

According to a statement in the Press, Mr. Cleveland Fyfe, Secretary of the National Farmers' Union, recently told a meeting of Cheshire farmers that, the Union "would resolutely fight compulsory pasteurization of milk."

Prof. A. T. Jurasz, Dean of the Polish Medical Faculty in the University of Edinburgh, cabling from the United States, announces that the Rockefeller Foundation has given $75,000 to buy medical instruments and equipment for the Polish Medical School.

Dr. James F. Ballard, director of the Boston Medical Library, completed fifty years of service on October 23.

Dr. John Harral Hudson of the Colonial Medical Service is reported to be missing in Malaya.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* the heavy fall in the notifications of infectious diseases that was reported can be partly accounted for by the Christmas week-end. The decreases recorded were for measles 2,394, scarlet fever 566, acute pneumonia 332, whooping-cough 323, diphtheria 277, cerebrospinal fever 32, dysentery 10.

The largest declines in the notifications of scarlet fever were for Lancashire 104, London 78, Yorks West Riding 76, Staffordshire 74, Middlesex 54. The greatest variations in the incidence of diphtheria were in Yorks West Riding, Durham, and Lancashire, where 59, 40, and 28 fewer cases were recorded. The only changes of note in the county totals of whooping-cough were decreases in Yorks West Riding of 45 and in London of 30.

The fall in the notifications of measles was general throughout the country, and only a few counties failed to register a decline, the only exceptions of note being Sussex and Bedfordshire with rises of 45 and 33. The largest declines were those of Yorks West Riding 459, Lancashire 274, Staffordshire 221, Nottinghamshire 201, London 198, Derbyshire 186, Wales 184, Leicestershire 183, Durham 179.

A general fall in the notifications of dysentery was recorded, and only in Surrey was there an appreciable rise from 3 to 16. The other chief centres of infection were Lancashire 20, London 15, and Essex 9. Only 5 cases were reported from Middlesbrough C.B., the lowest weekly total since the outbreak began fifteen weeks ago.

In *Scotland* a general fall was reported in the incidence of infectious diseases, especially measles, of which 237 fewer cases were recorded than in the preceding week. The largest of the local declines were Glasgow 61 and Dundee 58. In Glasgow 104 cases of scarlet fever were notified, an increase of 12.

In *Eire* the outbreak of poliomyelitis persists, and 10 cases from nine areas were reported during the week.

Small-pox

The risk of small-pox spreading in Edinburgh is now considered to be over. The ban imposed on Nov. 13 on visitors to the municipal hospitals was lifted on Jan. 4. The outbreak, which began on Nov. 1, resulted in 36 cases, 12 of which are still in hospital, and 8 deaths. In Edinburgh approximately 274,000 vaccinations were performed—about 64% of the population.

Returns for the Week Ending January 2

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 2,159, whooping-cough 1,187, diphtheria 939, measles 14,989, acute pneumonia 936, cerebrospinal fever 95, dysentery 95, paratyphoid 7, typhoid 6. One case of small-pox was notified in the rural district of Plympton St. Mary, Devonshire.

No. 51

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Dec. 26.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

---

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Includes paratyphoid A and B for Northern Ireland.

‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

The Services

The D.S.C. has been awarded to Temp. Surg. Lieuts. J. I. A. Jamieson, G. C. McKinlay, and I. Miskelly, R.N.V.R., and to Temp. Surg. Lieut. J. C. Gray, R.C.N.V.R.

The M.C. has been awarded to Capts. J. C. Bishop, M. C. Fulton, A. R. Wilson, and J. W. MacMillan, and Lieut. D. T. Milnes, R.A.M.C

Surg. Lieut. J. W. Wood, R.N.V.R., has been mentioned in dispatches for good services in the Mediterranean.

Temp. Surg. Lieut. E. O. Davies, R.N.V.R., has been mentioned in dispatches.

Surg. Lieut. G. A. Hendry, R.C.N.V.R , has been mentioned in dispatches (posthumous).

Squadron Leaders Agnes C. Gillan, G. B. Grayling, H. G. Magill, and J. St. C. Polson have been mentioned in dispatches by Air Officers Commanding-in-Chief, and F/O J. Dougall has been commended for brave conduct.

The King has approved the award of the R.N.V.R. Officers' Decoration to Surg. Cmdr. R. Wear and Acting Surg. Cmdrs. R. S. Allison and A. R. Thomas, R.N.V.R.

Brig. G. B. Chisholm, M.C., Director-General, Canadian Medical Services, has been appointed C.B.E. (Military Division); Lieut.-Col. M. H. Brown, R.C.A.M.C., an O.B.E. (Military Division); and Capt. (acting Major) H. E. Foex and Capt. H. C. Hair, R.C.A.M.C., M.B.E. (Military Division).

CASUALTIES IN THE MEDICAL SERVICES

Surg. Lieut. Kenneth Cole Jeffery, R.N.V.R., is reported "missing, presumed killed" on active service. He was born on June 17, 1909, the son of the late Surg. Capt. T. W. and Mrs. Jeffery, and was educated at the University of London and at the London Hospital, graduating M.B., B.S. in 1932, also taking the M.R.C.S., L.R.C.P. in the same year. He held posts at the London Hospital and the County Mental Hospital, Maidstone, before settling in practice at Sidmouth, where he became honorary physician to the local cottage hospital. Soon after the outbreak of war he entered the R.N.V.R., and in Sept. last was awarded the D.S.C.

Col. William Bruce, O.B.E., R.A.M.C., died in North Africa in December, aged 55. He was the third son of the late Mr. James Bruce, W.S., of Edinburgh, and was educated at Edinburgh Academy and at the University of Edinburgh, where he graduated M.B., Ch.B. in 1911. Not long afterwards he went to live at Onehunga, New Zealand, and served in the N.Z.M.C. from 1914 to 1920, attaining the rank of major. He was appointed O.B.E. in the 1919 New Year Honours for valuable services rendered in connexion with the war. In 1920 he entered the R.A.M.C. as capt., was promoted major in 1927, and lieut.-col. in 1941. He leaves a widow.

Lieut. Dudley Vaughan Phillips, R.A.M.C., who died on Jan. 4 at a battle school in Scotland as the result of an accident, was born on May 4, 1917, the son of Mr. and Mrs. Vaughan Phillips of Cyncoed, Cardiff. He was educated at the University of Cambridge, where he took the degree of M.A., and at St. Mary's Hospital, qualifying M.R.C.S., L.R.C.P. in 1942. He entered the R.A.M.C. in September last.

Prisoners of War.—Capt. A. Y. Adam, R.A.M.C., Capt. R. H. Cuthbert, R.A.M.C., Lieut.-Col. F. H. A. L. Davidson, I.M.S., Lieut. A. L. Dunlop, R.A.M.C., Capt. G. A. F. R. Gibson, R.A.M.C., Major P. R. Graves, R.A.M.C., Capt. J. K. Hewat, R.A.M.C., Capt. G. K. Marshall, R.A.M.C., Col. D. S. Middleton, R.A.M.C., Major W. J. E. Phillips, R.A.M.C., Capt. W. J. Street, R.A.M.C., Capt. K. W. Todd, R.A.M.C., Capt. R. G. B. Young, R.A.M.C.

Wounded.—Prob. Temp. Surg. Lieut. J. A. Oddie, R.N.V.R.

DEATHS IN THE SERVICES

Col. Henry Walker Murray, late R.A.M.C. (ret.), died at Tunbridge Wells on Oct. 25. He was born at Limerick on May 12, 1854, and was educated at Trinity College, Dublin, where he graduated M.B. in 1878, also taking the M.R.C.S. in 1879. Entering the Army in 1880, he became colonel in 1908, and retired in 1911. He served in the South African War from 1899 to 1902 and took part in the relief of Kimberley and in operations in the Orange Free State, including the actions of Magersfontein, Paarde Berg, Dreifontein, Poplar Grove, and Witte Bergen, receiving the Queen's medal with four clasps and the King's medal with two clasps. In the war of 1914-18 he rejoined for duty from October, 1914, and served as A.D.M.S., first at Bedford and later at Chatham.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, London, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be sent to the Secretary.

Telephone No.—B.M.A. and *B.M.J.*: EUSTON 2111.

Telegraphic Addresses.—EDITOR, *Aitiology Westcent, London;* SECRETARY, *Medisecra Westcent, London.*

B.M.A. Scottish Office: 7, Drumsheugh Gardens, Edinburgh.

QUERIES AND ANSWERS

Income Tax

Dissolution of Partnership

"Alpha" writes: A and B were in partnership, practising from their respective surgeries, sharing the gross fees equally but each paying his own surgery expenses. As from April 1, 1942, the partnership was dissolved with each partner taking over his own patients and practising as from his own surgery. How should the assessment for 1942-3 be calculated?

⁂ It has been judicially decided that for income-tax purposes there cannot be successors of parts of a concern. In this case neither A nor B has succeeded to the practice formerly carried on by them in partnership or is engaged in *that* practice. As a result that practice must be regarded as having ceased as from March 31, 1942, and A and B are assessable for 1942-3 on the basis that they have commenced separate practices as from that date—i e., they will be assessable on the basis of the earnings of the current year.

Hospital Appointment: Board and Lodging

K. F. holds an appointment "at a salary of £350 a year plus £100 in lieu of board and lodging." Should the £100 be included in his income-tax return and is it taxable?

⁂ The answer to both questions is "Yes." The amount is undoubtedly an emolument of office; the point K. F. probably has in mind is that where board and lodging are given in kind the value is not taxable on the recipient, but such cases are exceptions to the general rule.

Private Fees after Retiring from Public Appointment

"E. M. D." retired on Aug. 31, 1941, and since then his income has consisted of his pension plus "private fees for mental deficiency work." This work consists of examinations, and he is paid for it "per case." Since giving up the appointment "E. M. D." has had to renew some books and a number of old examination instruments. How should such fees be assessed and is he entitled to deduct these renewal expenses?

⁂ It seems clear that "E. M. D." does not hold appointments in the sense in which that test is applied in deciding whether liability falls under Schedule E, and in our opinion he is chargeable under Schedule D. Rule 3 (*h*), applying to Cases I and II, Schedule D, provides for the deduction of sums actually expended "for the supply, repairs, or alterations of . . . articles employed for the purposes of the . . . profession," and the renewal of professional books and instruments falls within that description.

Powers of Inspector of Taxes in Eire

J. C. has made returns of income for 30 years. At the request of the inspector of taxes he has employed a chartered accountant and has supplied copies of his bank accounts, etc. He has been asked to explain what he did with various sums of money, withdrawn at different times, amounting to about £1,000, but cannot now remember sufficient of the facts to do so. The inspector has now made assessments for 30 past years to bring these sums into assessment.

⁂ In making these assessments the inspector is acting within his legal powers, but J. C. has, of course, a right of appeal to the Commissioners and *prima facie* he would be well advised to exercise it. It is difficult to see why the inspector should be so concerned as to what was done with the money withdrawn from the bank accounts; provided J. C. can show that the amounts paid in to the account came from sources which were either not liable to income tax or had paid income tax, there should be no ground for now claiming tax on them. As a minor point, the inspector is not entitled to demand the employment of an accountant, but that is very frequently the best course to follow in these circumstances.

LETTERS, NOTES, ETC.

Treatment of Impetigo

Dr. ARTHUR F. CHALKLEY (Caistor, Lincolnshire) writes: There has been a good deal of correspondence recently upon the treatment of impetigo contagiosa. While I was serving in the Army in 1941 I had the opportunity of trying the various forms of treatment, as I had a small hospital for skin diseases. Of late I have had such rapid results from using sulphonamide and calamine ointment that I feel I should report the fact now when so many people are working in large numbers in proximity in different parts of the country. I have used ung. hydrarg. dil., eau d'Alibour, sulphanilamide powder with Lassar's paste, sulphur in calamine, but none has brought about healing so quickly as the following, which I do not remember having seen described; I find it very satisfactory for the treatment of children. I give the mothers a few tablets of *p*-aminobenzene-sulphonamide (0.5 gramme), and instruct them to crush a tablet and shake the powder over each lesion after removing the crusts with starch poultices, and then to put a thick dab of the calamine ointment over each one. This is repeated at least twice a day and more often if any lesion becomes bare. The results are strikingly good. I have also tried covering small lesions with pieces of elastoplast, which is fairly satisfactory.

Universal Decimal Classification

We are asked to notify readers concerned with the abstracting of scientific and technical literature, the compilation of bibliographies, or the classification of scientific documents, that the following parts of the English edition of the *Universal Decimal Classification*, all stocks of which were destroyed by enemy action, are being reprinted by the British Standards Institution with minor amendments:

Vol. 1. Part 1. General Introduction, Auxiliary Tables, and Class O, Generalities
Vol. 2, Part 1. Classes 51, Mathematics; 52, Astronomy; 53, Physics
Vol 2, Part 2 Class 54, Chemistry
Vol. 2, Part 3 Classes 55, Geology and Geophysics; 56, Palaeontology; 57, Biology; 58, Botany; 59, Zoology

Vol. 1, Part 1, will be published at 7s. 6d., and Vol. 2, Parts 1, 2, and 3, at 10s. per part. Owing to the restrictions imposed by the Paper Controller, the edition will be strictly limited, and the B.S.I. wishes to ascertain the probable extent of the demand for the various parts. Prospective purchasers should therefore make their requirements known as soon as possible. Orders should be addressed to the Publications Department, British Standards Institution, 28, Victoria Street, S.W.1.

"The Accurate Diagnosis of Small-pox"

Messrs. ASH AND CO. LTD. (London, S.E.1) write: In consequence of the letter by Col. S. G. S. Haughton (Dec. 19, p. 736) we have received applications for *The Accurate Diagnosis of Small-pox* by the late Dr. Wanklyn. We printed this pamphlet in 1928, and since 1931 have had but two applications for it; consequently during the paper salvage drive we destroyed the remainder we had in stock, so that we are unable to supply any of these.

Hypnosis

Dr. L. H. EUNSON (Tipton, Staffs) writes: Dr. A. Owen-Flood replies (Nov. 14, p. 596) to my comment on your leading article on hypnotism, asserting that it is evident that I have not made a deep study of the subject, and he thinks I emphasize its evils. It is evident he has not made a deep enough study of my comments to make himself sufficiently appreciative of their meaning, and by not understanding them he misinterprets them. He subsequently condemns this misinterpreted view by actively supporting the therapeutic value of hypnotism, on which I made no depreciation, and assumes some attendant evils of which I am not aware. What I did say was that there was a degree of relationship between the hypnotic state and the transference state obtained in the early stages of psycho-analysis, and I explained, by quoting Ernest Jones, that psycho-analysis proceeds to its ultimate goal via the subsequent stage of rendering transference conscious, whereas hypnosis does not do so. It is to Jones that we owe the observation that in hypnosis increased resistance to the necessary association of ideas occurs, and that psycho-analysis cannot proceed via hypnosis. I hope it is now quite clear to your correspondent that such a statement takes no exception to the therapeutic value of hypnotism in the minor maladies he quotes. I agree with his views. Like most of our eminent writers on this subject, however, he will find that if he proceeds to the treatment of the severe degrees of neurosis the results obtained are capricious and evanescent. Your correspondent's letter assures me I was correct in suggesting that more emphasis could have been given to this point, and my object in writing the letter was to obtain the viewpoint of others through the medium of your columns.

Headaches and "Silent" Sinusitis

Dr. SYDNEY PERN (Ballarat, Australia) writes: I read Dr. Craig's remarks on this subject (Aug. 22, p. 230) and it may be of interest to record my own experience. In 1925 I published a paper in the *Medical Journal of Australia* on the relationship of sinusitis to disease. I found that no less than 25% of patients attending my medical out-patient departments were suffering from sinusitis. I soon found that relying upon *x*-ray examination was of little use, but that if a patient had any creamy or yellow discharge from the nasopharynx persistently it was a definite sign of sinusitis. This in the majority of cases was accompanied by a history of morning headaches, frequent blocking of nose, and repeated colds. In chronic cases there may be only a little yellow discharge once or twice a week, which, if persistent, is still diagnostic. There are, however, some cases in which one cannot even get this history, yet other symptoms are sufficient on which to make a diagnosis. Blocked sinuses are more common than is realized, and these, as well as discharging sinuses, are responsible for far more ailments than is at present recognized. I have personally seen many cases of anxiety neurosis cured by treating the sinuses. I have seen patients sent to the mental hospitals on account of the same thing. I have cured many cases of exophthalmic goitre by clearing up sinus infections as well as chronic bronchitis and asthma in children and adults. A number of cases of retrobulbar neuritis have been cured by adequate sinus treatment. My own experience after many years has led me to believe that, of all the causes of headache, sinusitis probably accounts for 75%. Headaches due to eyestrain are usually felt in the evening, while sinus headaches are experienced on waking in the morning

Rectal Administration of Sulphonamides

Dr. H. G. J. HERXHEIMER (Westward Ho!) writes: The use of the sulphonamides grows daily. On the other hand, if they are given orally in the proper amounts they often cause nausea and vomiting or at least total loss of appetite, even if the usual precautions (sod. bicarb. or glucose) are taken. In order to avoid this disturbing side-effect I have given these drugs during the last 2 years to more than 25 patients rectally, as a small retention enema. The procedure is simple. Four half-gramme tablets of sulphanilamide or other drugs of this group are put into 1/2 to 1 oz. of lukewarm water, where they quickly disintegrate and will form, if stirred well, a thick, milky suspension. This is injected by a short-nozzled syringe into the rectum. The patient should afterwards go into knee-elbow position for half a minute. The suspension does not irritate and is easily retained. There are no side-effects. I feel compelled to publish this note, as this mode of application seems generally unknown in spite of its simplicity. It avoids sickness and even loss of appetite, and the accuracy of the dosage will not be disturbed by vomiting. The therapeutic effect, however, is the same as if given orally, as can easily be seen from its influence on the temperature curve. Of the drugs in question, sulphathiazole and sulphapyridine give a very good suspension, whereas sulphanilamide proper—at least one well-known brand which I used—sedimentates rather quickly, and must be used immediately after the preparation of the suspension.

An Adapted Cork

Dr. J. L. BARFORD (Guildford) writes: You published on Oct. 4, 1941 (p. 480), a brief description of my device for washing contaminated eyes. Briefly, a cork has about 4 inches of soft rubber tubing of ordinary douche-can diameter passed through it eccentrically and another small hole is bored in it for the entry of air. This device can be used to great advantage also for giving sips of water to "shocked" casualties, who could easily suck a little water through the rubber tube while lying supine. Obviously it is likely to be more useful for this purpose than for washing eyes. The cork is kept in a small calico envelope attached to the water-bottle. Some difficulty may be experienced in boring the cork, and it is advisable to use a proper cork borer. The cost of the corks is about 3½d. a dozen. I am informed that Messrs. Boots have made many of these adaptations for certain local authorities.

A Disclaimer

Dr. C. G. EASTWOOD, medical officer of health for Weston-super-Mare, asks us to state that he was not responsible for the reports that appeared in the lay press of a small, crude experiment in the control of the common cold which he was conducting among members of the local municipal staff.

GENERALIZED VACCINIA

BY

A. A. JUBB, M.D., D.Sc.
Medical Officer, Ministry of Health

The term "vaccinia" is used to denote the development and decline of an eruption at the site of inoculation with the virus of vaccinia, and the concurrent reaction of the body. Ordinarily the eruption is limited to that site, and occasionally "supernumerary" vesicles arise on the neighbouring skin. Rarely the eruption, with or without the supernumerary elements, appears also on other parts of the body, and this condition is known as "generalized vaccinia." The name is not good, because when vaccinia is running its course the virus becomes distributed throughout the body and vaccinia is therefore general (Cory, 1898; Committee on Vaccination, Report, 1928). "Vaccinal eruptive fever" was suggested, but in a successful Jennerian vaccination there is always eruption at the site of scarification, and usually there is some fever; on the other hand, apyrexia is not uncommon in generalized vaccinia. "Generalized cutaneous vaccinia" has been used, and is more satisfactory. There is convenience, however, in sticking to the designation that has been sanctioned by long use.

Vaccinia, therefore, is the normal result of a successful vaccination and is not a complication of vaccination, though generalized vaccinia may be regarded as such. Vaccinia is, in fact, a pathological entity with an exanthem, and like other exanthemata it has the stages of incubation, evolution, and decline; but as it is—to use the old distinctions—contagious and not infectious its eruptive capacity can be gauged only by the results of particular artifice and peculiar accidents. Generalized vaccinia has occurred in children who had sucked their vaccination pocks and in a child (though there is some element of doubt here) suckled by its mother, who was undergoing vaccinia. In persons previously insusceptible to ordinary vaccination it has been produced by the internal administration of vaccine crusts either ingested with food or insufflated into the nose. It has been produced in horses by the administration of vaccine lymph through the alimentary, circulatory, and respiratory systems (*Allbutt's System of Medicine*, 1912), and in other experimental animals by the intravenous injection of vaccine lymph (Blaxall, 1930). The number of these observations is very small and the proportion of eruptions very great compared with the vast number of human vaccinations that have run their course without a general eruption. To some degree, then, the occurrence of the condition is influenced by the route of invasion: the least provocative, or most inhibitive, is the skin, and the analogy to small-pox has long been recognized; for inoculated small-pox as practised during the latter part of the eighteenth century gave usually a much less general rash than did the disease acquired naturally through the respiratory passages, and might even not cause any eruption beyond that on and near the site of inoculation. This mildness cannot be claimed, however, for the inoculated small-pox of the preceding years, because then the eruptions were often profuse; in those years the inoculum was taken from cases of natural small-pox, whereas later it was invariably taken from persons undergoing the inoculated disease. Ledingham's explanation for the reduced amount of eruption is that the artificial propagation by arm-to-arm passage modified the character of the virus, perhaps towards the character of the virus of vaccinia, and he bases this view on the fact that small-pox can become vaccinia by repeated passage through suitable animals.

It has, however, been suggested that some amount of antibody was produced by the skin at the site of inoculation of small-pox and was a factor in attenuation of the induced attack. As to vaccinia, though it is true that immunity can be obtained without vesiculation, Henderson and McClean (1939) have shown that the skin is of some importance in the production of immunity—a view taken by F. R. Blaxall. They investigated the effect of intracutaneous and subcutaneous vaccination with a bacteria-free elementary-body suspension of vaccinia virus on the production of immunity as tested by a cutaneous (scarification) vaccination with ordinary vaccine lymph six weeks later. Of 164 persons vaccinated in either of the above ways with elementary-body suspension, 75 developed a vesicle and 72 of them were immune to vaccinia on subsequent testing; of the 89 who did not develop a vesicle 31 only were found to be immune. As to cutaneous scarification, the 22 persons inoculated thus with ordinary vaccine lymph produced vesicles and all were immune on testing later, and of 24 scarified and vesiculated with elementary-body suspension 23 gave in due course a satisfactory result in immunity. There was correlation, therefore, between vesicle production and immunity.

In the intravenous experiments with ordinary lymph referred to above, generalized vaccinia often did not result, but later on it was demonstrated that adequate intravenous doses of the lymph and, better still, of certain strains of the virus (neurolapine and neurotesticular lapine) could give rise to typical vesiculation on the skin and marginal mucous membranes of animals, including monkeys, cats, and dogs. After full doses of these strains the virus could be recovered from most of the internal organs, and macroscopic lesions were found in most of the viscera (Douglas *et al.*, 1929). Thus, by stepping up the dosage and using certain strains of the virus, generalized vaccinia can be made fairly constant in incidence and often severe in attack.

The dosage, strain, and to some extent the portal of entry are factors, therefore, in the production of generalized vaccinia in experimental animals. In human vaccination the dose is small, the lymph is a dermal strain the potency of which is far below that of the experimental strains of the virus, and the entry is by the skin. It seems thus to be the office of the skin that is in question: does its failure to produce antibody, or sufficient antibody, at the vaccination site result in generalized vaccinia? But in those human subcutaneous and intracutaneous vaccinations in which the intention of avoiding vesiculation has been achieved generalized vaccinia does not seem to be more prone to occur than in Jennerian vaccinations, and, for what it is worth, the observation can be made that in generalized vaccinia the vesicle of vaccination does not differ in development and aspect from those in normal cases. We may presume, then, that whatever be the relation of the vesicle to immunity, a lack—this is, a deficiency or an absence—of general response in immunity is the cause of the complication, if, indeed, a severe attack of an infection can be called a complication because it is rare.

Eczema Vaccinatum

Reference may be made here to eczema vaccinatum. This has been described as occurring in vaccinated persons with a history of attacks of eczema and in children suffering from eczema who, being in familial contact with someone undergoing vaccinia, had presumably been inoculated on the eczematous area through accident. An eruption of a vaccinial character appears on the eczematous site, which itself becomes intensely swollen and inflamed; the eruption may spread to healthy areas of skin, and when it is profuse the outlook is grave. Tedder (1936) considers that the conditions known as Kaposi's varicelliform eruption and pustulosis vacciniformis acuta are not only one and the same but are identical with eczema vaccinatum, and that failure to obtain a history of exposure to the vaccine virus has in most cases been the only reason for not identifying the former with eczema vaccinatum. It might be inferred, then, that an unhealthy state of the skin, some itching dermatosis, is the cause of generalized vaccinia, and, in alluding to Tedder, J. D. Rolleston (1937) gives the interesting fact that his own case of generalized vaccinia had recently suffered from varicella. A remarkable series of vaccinial eruptions on injured or diseased skin has been detailed by Nimpfer (1936). A child admitted to hospital with burns of the first and second degrees was vaccinated on admission; eight days later vaccinial pustules appeared on the burned surface. This was obviously the result of blood-borne virus; but thirteen days afterwards a patient in the same room and suffering from burns of the second and third degrees showed vaccinial lesions on the burnt surfaces, and ten days later a child with dermatitis, in a distant room but nursed by the same staff, developed generalized vaccinia. A fourth case, also of burns, developed vaccinial lesions six days later. Danziger (1907) recounted a similar occurrence in children affected variously with eczema and impetigo. These sorts of accident can be avoided by discretion in vaccination and care during vaccinia.

Though it is not disputed that a diseased or damaged part of the skin is vulnerable to direct infection by the vaccine virus, and perhaps also highly susceptible to the virus blood-borne (haematogenous) from the site of intentional vaccination, there is no evidence that generalized vaccinia—that is, the condition seen in the ordinary practice of vaccination—is due to a latent unhealthy state of the skin. Tedder's conclusion is: "True generalized vaccinia represents a disturbance (following vaccination) of the balance between the virus and the virucidal substances which it calls for in a person having an intact healthy skin, so that the virus which is disseminated haematogenously becomes active in the skin, producing a generalized vesico-pustular eruption, lesions on the mucosae, and general symptoms." As a balance can be disturbed to either side this statement is not precise, and its meaning can be put into three words—lack of antibody.

Incidence of Generalized Vaccinia

There is no doubt of the infrequency of generalized vaccinia. Numerous estimates of its incidence have been made, ranging from 1 in 10,000 to 1 in 100,000, and even 1 in 900,000 (Chaudhuri, 1940). For a considerable number of years all reports of cases of generalized vaccinia and other eruptions sent by the public vaccinators of England and Wales to Lieut.-Col. W. D. H. Stevenson, Director of the Government Lymph Establishment, have been subjected to special scrutiny, and to inquiry where deemed advisable, and the statistics so derived can be taken as ample for a fair computation. During the period July 1, 1932, to June 30, 1937, in 1,026,588 vaccinations 15 cases of generalized vaccinia and 11 doubtful cases were reported, giving, if the doubtful cases are included, an incidence rate of not more than 1 in 39,484 vaccinations (Shaw and Stevenson, 1939). If the doubtful cases are excluded the rate is 1 in 68,439. Since the publication of those figures a wider survey of the establishment records has been made by Stevenson and Cox; this covers four years—1909-10 and 1921-2—taken at random, and the period from July, 1932, to June, 1941. The total number of vaccinations reported by public vaccinators was 3,289,733, with 34 accepted cases of generalized vaccinia; 35 reported cases were considered on inquiry to be doubtful enough to warrant exclusion. The accepted cases gave, therefore, an incidence rate of 1 in 96,756, with 4 deaths—a fatality rate of 11.7% and a mortality of 1.2 per million vaccinations. There was no death among the rejected cases.

Some years ago a questionary on the incidence of generalized vaccinia was addressed by the Ministry of Health to 28 public vaccinators selected on account of their long experience in vaccination. Replies were received from 26; of these, 17 reported that they had seen cases "occasionally" or "not for some years," or that they had seen one case within a stated period. Three had not seen a case in, respectively, 32, 28, and 27 years. As to supernumerary vesicles, one vaccinator was of the opinion that they occurred in less than 1% of vaccinations; another had not seen any in 27 years; and a third had not had more than 6 instances in many thousands of vaccinations.

Incidence in Adults.—It is widely believed that generalized vaccinia is more rare in adults than in children. Only 1 patient in the above 34 was beyond childhood, and was aged 17 years. The number of adult vaccinations reported by the public vaccinators is not available from our central records, but it can be said that in a period of several years during which nearly four million doses of lymph for adult use were issued by the Government Lymph Establishment only one instance of generalized vaccinia was reported among those adults. The experience of Froumy, reported by Haslund and quoted by Anders (1919), is surely unique. He vaccinated 175 cadets, all of whom had been successfully vaccinated in earlier life; of these, 64 had normal vesicles, 56 had small vesicles, and 55 were unsuccessful. Of the 64, 8 developed an eruption that may have been vaccinial, and 12 developed typical vaccinial pustules on face, trunk, and extremities; in 4 of the 12 the eruption was considerable, and it appeared even on the mucous membranes.

Secondary and Tertiary Vaccinations.—There is no record at the Ministry of generalized vaccinia in secondary or tertiary vaccinations, but Froumy's cases show that secondaries may not be exempt; and an instance in a tertiary was published by Stewart (1902). The risk is, of course, inversely proportional to the amount of immunity remaining from the previous vaccination.

Vaccinial Rashes

The various kinds of vaccinial rashes sometimes cause difficulty in diagnosis when small-pox is present in the district. During the small-pox epidemic of 1902 Chalke (1931) made a study of these, and he concluded that by far the greater number were accidental and either were in the nature of serum rashes (erythematous, scarlatiniform, morbilliform, and urticarial) or were due to the absorption of toxic products from the vaccinial site; that other symptoms of serum disease were not often encountered and the introduction of a small amount of serum in the operation of vaccination did not act as a sensitizing dose; and that vaccinial rashes of any type were rare among revaccinated subjects.

The rashes reported to the Ministry have been described by the public vaccinators as papular, pustular, punctate, erythematous, morbilliform, urticarial, roseolar, eczematous, and macular. From the records of six consecutive years Stevenson has computed that the incidence of all rashes, including generalized vaccinia and supernumerary vesicles (but excluding rashes near the vaccination vesicle and probably due to faulty dressings), was 1 in 7,755 vaccinations. It must be noted, however, that the occurrence of a vaccinial rash after a public vaccinator has ceased his routine visits to a normally progressing case of vaccinia may not be brought to his knowledge, particularly if the rash is mild and evanescent; doubtless, therefore, the true incidence is somewhat greater. But in a recent period of mass vaccination in Glasgow a ratio approximately as high as 1 in 4,000 was recorded; no instance of generalized vaccinia was found in a total of about half a million vaccinations (Bloch, 1942).

One case of mild pemphigus, one of petechial rash, and two of purpuric rash have come to our notice, but purpura associated with vaccination is very rare; the number of recorded cases is probably less than a dozen, though Heaton (1940), in reporting a case, quotes a statement of Trant that the occurrence was noted as long ago as 1842. In the experience of Stelwagon (1902) the most frequent generalized manifestation was "a mixed type of urticaria and erythema multiforme, or better described as an erythema multiforme with often itching and other features of urticaria." It is probable that in the majority of instances the vaccinial rash is anomalous in its being a mixture of lesions and not a single dermatosis, and possible that allergy is an important factor in causation.

Vaccinial rashes may appear at any time in the course of vaccinia from the day after vaccination, the earliest being mainly the erythematous and urticarial, but the incidence of rash is low in the first week, and available figures indicate that the majority—say 80%—develop in the period from the 7th to the 11th day after vaccination.

Generalized vaccinia has no prodromal rashes: the occurrence of a rash prior to or along with the specific eruption is fortuitous. It is only a papular rash that should raise suspicion of generalized vaccinia, and even then the diagnosis should, as Shaw and Stevenson suggest (1939), be withheld unless the papules proceed to vesiculation. The eruption usually affects the trunk more than the limbs and, as mentioned before, it may appear on the mucous membranes. In a fatal adult case reported by Anders (1919) the eruption had extended to the trachea. Turnbull (1941) has published an unusual case of dysphagia due to swelling of the tongue caused by the eruption on it of two vesicles; the case, which was fatal, is of interest because of its extreme rarity. The only previously recorded instance of interference with feeding appears to be that of a case brought to the notice of the Royal Commission on Vaccination (1896); the presence of vesicles in the mouth prevented the infant from sucking, and death ensued.

Concurrence of Generalized Vaccinia and Post-vaccinial Encephalitis

The concurrence of two conditions so rare as generalized vaccinia and post-vaccinial encephalitis must be a very remote chance—one in many millions—and only 8 cases appear to have been described or mentioned. One reported by Weichsel (1931) may be accepted. A fatal case described by Paisseau and Scherrer (1929) had singular symptoms: the legs from the knees downwards and the feet were cold and blue, the forearms and hands were cold and blue, almost black. The general eruption consisted of 3 pustules near the vaccination pustules, 1 on the back of the arm, 1 near the axillary fold, and 1 on the upper part of the back—a distribution that hardly escapes from the category of supernumerary vesicles. These authors mention, without traceable reference, a case of generalized vaccinia and post-vaccinial encephalitis that had been published before theirs. Jorge (1927), on the authority of Garret, gave an account of a case of vaccinial eruption with meningeal symptoms, followed by blindness and deafness, that cleared up after five months. Jorge also mentions an encephalitic case of Netter and Cestas's in which a vaccinial eruption appeared on the thigh 14 days after vaccination; the site of vaccination is not stated. Mexico, however, provides the most remarkable record. In that country 8 cases of post-vaccinial encephalitis were reported in the decennium 1928-37; of the 4 that recovered, 2 had residual paralyses with mental disturbance and 1 had residual deafness. The patient with residual deafness, and 2 of those who died, had generalized vaccinia.

In England and Wales only one instance of the suspected concurrence of the conditions has been brought to our notice, and after inquiry it was concluded that neither of them existed. Case 114 in the Further Report (1930) of the Committee on Vaccination may, however, be a true instance.

Generalized Vaccinia of the Foetus

Though vaccinia rarely influences the course of pregnancy there is considerable evidence that vaccination late in the pregnancy confers some degree of immunity on the foetus; but the immunity is transient, and is lost in a few weeks after birth. There does not appear to be any record of generalized vaccinia in a pregnant woman, and therefore much interest is attached to accounts of foetal eruptions following vaccinia in the mother. Lynch (1932) has published an account of an eruption, which he calls "pemphigoid vaccinia," in the premature and short-lived child of a woman vaccinated 27 days before the birth, and he is of the opinion that similar cases have been described in the past as intra-uterine variola. He has collected 8 cases from the literature, beginning with one recorded by Jenner; in all of them, as in his case, the mother was vaccinated because of the presence of small-pox either in the home or in the district, and none of the mothers developed a variolous eruption. If we reject one case (Siebold's) as too fanciful for credence it appears that the births took place from two to ten weeks after vaccination and that, of the 7 infants, 4 were stillborn, 1 was non-viable (5th month), and 2 died soon after birth. That these mothers passed through vaccinia and variola sine eruptione with variolation of the foetus is a probability too distant for contemplation, and in the light of Lynch's informative discussion it is reasonable to regard these as instances of generalized vaccinia of the foetus.

Auto-inoculation (Auto-vaccination)

Auto-inoculation is not generalized vaccinia; it is the result of the transfer of virus from the vaccination vesicle to one or more places on the skin, almost invariably by the fingers of the vaccinee and inoculated by scratching. For diagnosis the sites are suggestive, being commonly the face and the front of the body. Auto-inoculation sometimes induces generalized vaccinia; in this event, pocks do not cease to appear after suitable precautions have been taken, but continue to arise for as long, perhaps, as five or six weeks. The condition known as eczema vaccinatum has already been mentioned.

Post-mortem Findings

In the generalized vaccinia produced in rabbits by intravenous inoculation, usually of extremely active strains of virus in very large doses, lesions have been found in the lungs, liver, spleen, and suprarenals. In human generalized vaccinia there has not been the introduction of an overwhelming dose or of a virulent strain; the reaction is due to an inherent susceptibility and, as in other acute infections, death can ensue from toxaemia rather than from visceral damage. In a case examined by Dible and Gleave (1934) there was some oedema in the lungs and congestion of the bases, otherwise the respiratory system was normal, and so was the heart. The liver showed two small white, solid areas, each about 3–4 mm. in diameter; both were on the surface and visible beneath the peritoneal coat. Apart from some slight fatty infiltration the organ showed no other change. In the spleen there were some congested areas but no other visible abnormality. The remaining abdominal organs exhibited no naked-eye changes. The central nervous system showed general congestion but no other naked-eye lesion. The lesions in the two pocks in the liver were almost pure necrosis with karyolysis of the liver cell nuclei and a rapid conversion of the tissue into a granular unstaining mass; the lesions were as sharply delimited as the pocks in the skin. The spleen had a considerable number of necrotic foci, the largest 0.5 mm. in diameter; their histological appearance corresponded to that described in the liver and skin—the same pure sharply circumscribed necrosis, absence of reaction, minimal infiltration with leucocytes, and karyolysis of most of the nuclei: briefly, pure necrosis without haemorrhage and with a minimum of reactive change. No lesions were seen and no virus was demonstrated in the brain. The authors point out the similarity of the epithelial lesions to those of the older descriptions of small-pox lesions rather than to those produced in thin-skinned experimental animals such as the rabbit.

Diagnosis

The virus of vaccinia has been demonstrated in the blood as early as the third day after vaccination; on the other hand, it has been shown that the excision of a normally progressing vaccination site as late as the fourth day can prevent the full development of immunity. In theory generalized vaccinia is a late starter; it cannot be ahead of the local vaccinial reaction, and in practice it rarely runs equal. The fourth day after vaccination may be taken as the earliest day of appearance, and by far the commonest period is from the ninth to the fourteenth day. Delay to the twenty-third has been reported, as in Froumy's case, and in this curious event it must be supposed that immunity had not been firmly established. The end-point of cropping is indefinite; the eruption does not ordinarily go beyond one crop, but new crops may appear up to five or six weeks, though this is unusual. By Cory's law the time taken in the maturation of pocks should be inversely proportional to the degree of immunity, and rapid maturation of new pocks will indicate that immunity is being developed. In diagnosis the following considerations will be helpful:

1. Auto-inoculation should be excluded.
2. The eruption does not appear earlier than the fourth, and seldom earlier than the ninth, day after vaccination.
3. The eruption must be elsewhere than in the neighbourhood of the vaccination site.
4. There must be a vesicular stage.

The eruption may arise on any part of the skin—limitation to one sole has been reported—and within the mouth. The distribution is not specific, and any resemblance to that of small-pox is accidental. When profuse the elements may show much diversity in size, up to that of a sixpence or even larger, as contrasted with the almost uniform size seen in discrete small-pox.

Treatment

In some quarters it is the practice to seek to prevent severe reactions in adult primary vaccinations by puncturing and evacuating the vesicle on the seventh or eighth day after vaccination and applying a dressing of permanganate of potash. This is not free from the risk of impairment of protection, as immunity against small-pox is not satisfactorily established before the ninth day and it would not be justifiable as an attempt to prevent the unusual complication of generalized vaccinia. Mervyn Gordon (1941) has suggested, however, that permanganate of potash, to which the viruses of both vaccinia and small-pox are extremely susceptible, might be effectively used in treatment by the application of a wet compress of the permanganate solution to the vesicles of the eruption. Even in a dilution of 1 in 100,000, he states, permanganate can inactivate the vaccinia virus, but glycerin should not be added, for it inhibits the virucidal action. He advises also that in a severe case trial should be made of serum from a recently vaccinated person—a treatment which, in fact, he was the first to suggest in post-vaccinial encephalitis. The most potent serum, in his opinion, would be that taken from young healthy adults 14 days after vaccination.

An account of a case of mycotic endocarditis has been given by A. Wikler and his colleagues (*J. Amer. med. Ass.*, 1942, **119**, 333). The patient was addicted to heroin and had a mitral lesion. On two occasions during his life blood counts yielded a yeast-like growth subsequently demonstrated to be *Candida (Monilia) parakrusei*. The authors believe that careful laboratory work ruled out the possibility of contamination of the culture medium, and point out that during the past two years 5 cases of mycotic endocarditis have been recorded in cases of drug addiction; in 4 of these the infecting organism was *Candida parakrusei*, and in the fifth *C. guillermondi*. The authors were unable to isolate *Candida* from samples of heroin, and point out that this fungus is frequently found on the surface of the skin.

THE PROGNOSIS IN CIVILIAN HEAD INJURIES

BY

ERIC GUTTMANN, M.D., L.R.C.P.Ed.

(From the Nuffield Department of Surgery and the Accident Service, Radcliffe Infirmary, Oxford)

The prognosis of accidents depends on many non-medical factors. Besides the results of organic damage there are social and psychological factors which profoundly influence the patient's health, happiness, and working capacity after an accident. Prognostic studies in the past have taken little account of these factors, though many discrepancies in recorded numerical results probably depended on such influences as the condition of the labour market at the time, the system of social insurance, and their consequent social and psychological effects.

The Accident and Rehabilitation Services which have recently been developed owe their existence largely to such considerations. In the publications on their organization, methods, and result very little reference has been made to the problem of head injuries, though the importance of these is far from negligible. Not only is their proportion among the accident admissions considerable—at this hospital about 30%—but their after-effects are generally regarded as serious in character and difficult to assess. It seemed of interest, therefore, to study the prognosis of head injuries, particularly at a time of comparatively standardized and favourable social conditions, when everybody has the choice of well-paid jobs and most employers are ready to facilitate gradual return to work.

All cases were treated by an active method of early rehabilitation. No patient was told to keep quiet; if he did so on account of unpleasant sensations he was early encouraged to move his head and body freely, to sit up, and, after a few days, to get out of bed. Lumbar puncture was carried out only where desirable for diagnostic purposes, and no dehydration was employed. Elsewhere I have described how, with this form of treatment, these patients suffered but little from headache (Guttmann, 1943). The same paper gives details of the severity and type of the accidents. The present paper deals with the results of the treatment on the loss of working time. Some references to earlier publications on the prognosis of head injury are appended. The figures reported are not easily comparable on account of the differences of time of follow-up, the proportion of cases re-examined, and the social conditions. Only Ritchie Russell (1932) has given a detailed analysis of similar material, and his figures are quoted on p. 95. But his patients were kept in hospital for at least three weeks.

Material

This paper is based on 300 consecutive admissions of head injury; among these were 255 civilians available for study. These cases, it must be emphasized, were the unselected accidents, mainly road accidents, of a mixed urban and rural area. Ten patients out of the 255 (4%) died; of the remainder 2 were permanently incapacitated owing to cerebral damage. The duration of the in-patient treatment is given in Table I.

TABLE I.—*Duration of In-patient Treatment (245 Cases)*

Up to 1 week	125
„ 2 weeks	76
„ 3 „	22
„ 4 „	12
Longer	10

Table I shows that just over 80% of all cases were discharged from hospital within two weeks of admission. Among the 245 incapacitated patients are included all cases with injuries elsewhere: 73 had major injuries, such as fractures of bones. All cases of mild head injury (i.e., with a post-traumatic amnesia of one hour or less) were treated in hospital fourteen days or less; three-quarters of the cases of moderate severity (post-traumatic amnesia up to 24 hours) and one-half of the severe cases (post-traumatic amnesia over 24 hours) were discharged within the same period. All cases which stayed in hospital four weeks or longer did so on account of complications, such as fractures of the spine, pelvis, or extremities. After discharge from hospital the patients returned for further treatment to their own doctors, to whom a letter was sent. They came back to hospital for re-examination at a date when they were expected to be fit for work, and again three months and six months after the accident. Patients who failed to keep these appointments were followed up by the department's social worker. Table II gives the social classification of the patients.

TABLE II.—*Social Classification*

	Number
Children under school age	12
School children	29
Housewives, excluding married women going out to work ..	25
Wage-earners, including aforementioned	158
Owners of businesses	12
Not working, including chronic invalids	9

Results

All housewives returned to their work; but as their duties varied very much from case to case, as did the amount of help they received during convalescence, it did not seem possible to express their time off work in precise figures. The school children will be discussed in another paper.

Of the 158 wage-earners, 19 could not be traced after the first follow-up appointment, and no information about their taking up work was forthcoming. Six patients returned to work during the follow-up period, but no exact information was available as regards the total working time lost by them. Three patients expected their call-up, and did not return to their previous work for that reason; they all joined the Services during the follow-up period.

The working time lost in 130 cases is given in Table III. It should be noted that all cases are included, whether they had injuries to other parts of the body or not. To compare the figures with those given by Ritchie Russell the respective tables have to be condensed, as under (Ritchie Russell's figures in brackets).

TABLE III.—*Loss of Working Time*

Weeks lost ..	1	2	3	4	5	6	7	8	9	10	11	12	13
No. of patients ..	4	18	10	18	18	7	9	10	3	4	2	4	5
Weeks lost ..	**14**	**15**	**16**	**17**	**18**	**19**	**20**	**21**	**22**	**23**	**24**	**25**	**26 and over**
No. of patients ..	—	1	1	1	—	—	3	1	1	1	1	—	8

Returned to work within 13 weeks	112	
Returned to work within 26 weeks or joined up	131	(110)
Not returned to work within 26 weeks	8	(29)

The crude average of the figures in Table III is 6.6 weeks, exclusive of those still off work at the end of the six-months period. Owing to the large scatter this average does not give a true picture, and it is fairer to say that 25% of the patients lost three weeks or less, 50% between three and nine weeks, and 25% more than nine weeks.

The low incidence of headache in these patients has been described in another paper (Guttmann, 1943). None of the patients relapsed during the first six months after the accident. Only those patients who had symptoms or signs at that date were given further follow-up appointments; apart from one case of post-traumatic epilepsy no patient reported any further loss of working time. Some of those off work after 26 weeks subsequently returned to their occupations.

Of the eight patients who did not return to work within 26 weeks only two were incapacitated by cerebral damage. Four were definitely neurotic, and a fifth very likely so. The last case showed neurotic symptoms superimposed on residual symptoms due to a fractured pelvis. Though other psychological factors could be found to account for the neurotic reactions, the compensation problem played a part in three out of the five non-organic cases. In order to see the importance of this factor in the correct light one has to compare these cases with the other occupational accidents. There were altogether 11 cases in this series with a claim under the Workmen's Compensation Act—the three cases mentioned and eight others. Of the latter eight cases six returned to work in 2, 3, 4, 5, 5, and 6 weeks respectively. Another case, off work for 10 weeks, was a serious injury with a post-traumatic amnesia of six hours. The last case was off for 16 weeks on account of a compression fracture of the spine. Claims against drivers and insurance companies arising out of road accidents were not here considered.

There was a higher proportion of compensation cases in Ritchie Russell's material; the mildly injured among them showed a tendency to stay off work comparatively longer. The lesser influence of the compensation in the present series may be due to the conditions of employment in wartime. But the number of cases is too small for any definite conclusions. The impression gained is that the compensation claim does not act as an incentive—conscious or unconscious—to produce a neurosis, but that in patients with latent difficulties the monetary compensation may enable them to stay off work when otherwise they might have put up with their symptoms. Delays and frictions in the compensation machinery increase and lengthen the neurotic symptoms. The psychological mechanisms have recently been described by B. Hart (1942), and the following case record illustrates some of them.

A carpenter aged 58 with a steady work record. While at work he fell down a 6-ft. hole. He was unconscious for a few minutes; his post-traumatic amnesia was 15 minutes. He had a fissure in his left temporal bone and a fracture of the right clavicle. Apart from slight nystagmus bilaterally, he had no neurological signs. He complained continually of some headache and giddiness, but was mostly handicapped by limitation of movement and pain in his right shoulder. This, he said, affected his head. The lack of power in his right arm was increasingly worse at subsequent examinations, though neither surgical nor neurological examination showed any objective signs to account for it.

On the day after the accident he was to have started in a new job for his firm. In order to see what this new job amounted to, he had opened the door to the stokehole where he was to work. No one had told him of the 6-ft. drop and iron stairs leading to the stokehole. This he still resented many months after the accident. At some medical examination he was told that there was nothing that medical treatment could do for him, and that he should find himself a lighter job. His comment was that he was a trade union man, and that so long as his compensation money was coming through he would sooner wait to be fit to resume his own job than take a light job meanwhile. He also had a grievance against the hospital because he was not seen by a particular doctor.

Of his previous history it is worth mentioning that he had not been fit for service in the last war on account of effort syndrome, and he had continued to suffer from this long after the war. He also mentioned spontaneously, in the course of the interview, that he never had much money to spend on himself, as all his three daughters had gained scholarships and he had to maintain them for the extra years, to pay for their training and so forth. The feeling that he deserved some rest and pay and consideration influenced his attitude very much.

Severity of Injury

The duration of unconsciousness is generally regarded as an indicator of the severity of a concussion. Ritchie Russell suggested using the duration of post-traumatic amnesia instead, as it is easier to assess. To test the prognostic value of this measure, the cases (excluding those patients kept off work by injuries to other parts of the body) were divided into four groups and the average off-work times calculated for each. Table IV shows clearly that the time off work increases with the length of post-traumatic amnesia (though only the difference between the first and the second group is statistically significant). Considering that the cases are entirely unselected, the figures may well be used as a prognostic guide: in other words, one may expect a patient with a post-traumatic amnesia of an hour or less

TABLE IV.—*Duration of Post-traumatic Amnesia and Loss of Working Time not affected by Injuries Elsewhere (105 Cases)*

Post-traumatic Amnesia	No of Cases.	Weeks	Difference	St. E.
Up to 1 hour	67	4·5 ± 2·08	1·10	0·539
„ 1 day	27	5·6 ± 2·46	3·25	2·078
„ 1 week	7	8·85 ± 5·34	4·90	3·084
Longer	7	13·75 ± 4·65		

to be fit for work in about four weeks; with an amnesia up to about 24 hours, within about six weeks; and with an amnesia up to one week, within eight or nine weeks. This, however, does not refer to penetrating injuries; about these and other pitfalls of the prognosis, in the light of the post-traumatic amnesia, the reader must be referred to Cairns (1941).

In all those with mild concussion who stayed off work for seven weeks or more, psychological factors could be found to account for the fact. A few short examples may illustrate the point.

A boy with a momentary amnesia stayed off work for eight weeks. The reason he gave was a trivial scar, which, he said, prevented him from cycling to his work. In fact, he was badly shaken by the terrifying experience of being squeezed between a van and a wall while cycling.

A woman with a head injury incurred in an attempt at suicide during the third attack of a recurrent depression stayed away from work on account of her depression.

A nervous woman given to bilious headaches all her life stayed off work on account of post-concussional headache; she was employed on strenuous war work in a factory, and had the obvious attitude that she deserved a good rest.

A man with a trivial concussion and a haematoma round his eye, with transient restriction of eye movement, developed psychogenic symptoms referring to his eye first and general depression and anxiety later.

A short survey of the small number of independent shopkeepers and business men (12 in all) confirms the view that late effects of head injury are more often due to social and psychological factors than to the physical effect of the accident. All but one had had accidents of moderate severity. Five returned to work within two weeks, four within two months. The latter were inclined to take it easy—one among them on account of a mild endogenous depression, another for the duration of the settlement of an insurance claim. The psychological factors operative in the three remaining cases were more complicated. The following is the history of one of them.

A man aged 34 had a concussion with a post-traumatic amnesia of about six hours. Apart from a few lacerations of the scalp he had a fracture of the right zygoma which caused no disability. He was discharged from hospital 16 days after the accident, complaining only of slight giddiness. When seen again three months after the accident he showed generalized tremor of the shell-shock kind and a hysterical astasia abasia. The patient was a man of moderate intelligence. Until a short time before the accident happened he had been a general labourer employed on construction of an aerodrome near the village where he lived. He had earned an unusual amount of money, and, on the advice of his clever brother-in-law, he bought a lorry and undertook work for the contractor on his own account. A fortnight after he had started the venture the accident occurred: an Army lorry ran into him and his lorry was badly damaged. The Army authorities assumed responsibility for the repair, but he had not succeeded in getting the repair work done and had not received any monetary compensation so far. Everything was in the hands of his brother-in-law and the solicitors. There were probably additional reasons for the hysterical reaction. The patient had previously had an accident which had been followed by a considerable time off work and continuous headache.

This case, which mostly resembles the picture of compensation neurosis, is probably more correctly interpreted as the patient's reaction to his life situation, with which he was not able to cope. His position as an entrepreneur was already beyond him, and the complications created by the accident made him break down. It is very unlikely that he could, or actually did, expect any financial gain, beyond compensation for his loss.

Comment

The analysis of all the cases—it must be emphasized again that they are the unselected total of cases of head injury admitted to this hospital—gives some idea in how short a time the average patient can be discharged from hospital and become fit to return to work under the social conditions characterized in the beginning of this paper. The figures of off-work time given for the groups of different severity are somewhat below those suggested for similar cases by Cairns, and this is not surprising in view of the different social setting (civilian as against Service cases). This does not mean that all patients were free from symptoms when they returned to work: the social prognosis is not identical with the medical prognosis. Some patients complained of headache and a few of postural giddiness for a varying length of time (Guttmann, 1943); but they were able to adjust themselves to their symptoms, just as they had adjusted themselves to headaches and other symptoms before the accident. Several showed, when examined psychologically, some impairment of their mnestic functions; but this did not prevent them from returning to their previous work and doing it efficiently and willingly. (Such patients may find themselves handicapped when they have to change their occupation and to adjust themselves to new conditions; but this did not arise in the present series: it is generally of greater importance in intellectual workers, who are in the minority among hospital admissions.) A few cases showed emotional changes (slight euphoria or emotional indifference) which did not interfere with their working capacity, and may, indeed, have helped in adjusting them to their symptoms. Where return to work was delayed beyond the average periods it could be shown that social and psychological factors, rather than physical after-effects, of the injury were predominantly responsible.

This points to the need for psychological management in the early stages and for facilities for psychological treatment and social after-care in the convalescence and afterwards. It is impossible to estimate to what extent the outcome in this series was influenced by the interviewing and follow-up arrangements; but one may assume that the procedure had some effect, since such psychiatric investigations inevitably lead to increased contact through discussion of some of the patient's problems and arrangements for his convalescent period, etc. One would anticipate that more systematic and intensive work along these lines would improve the social results not only in head injuries but in all branches of accident work.

Summary

A series of 300 consecutive admissions of head injuries to an Accident Service in a mixed urban and rural-district was investigated in regard to the social effects of the accidents. 4% of the patients died, and two became invalids through cerebral damage. Of the cases 80% were treated in hospital for 14 days or less. The average working time lost by wage-earners was roughly eight weeks. In mild cases (i.e., those with a post-traumatic amnesia of one hour or less) the average loss of working time was 4 to 5 weeks; in moderate cases (post-traumatic amnesia 1 to 24 hours) it was 5 to 6 weeks; in severe cases (post-traumatic amnesia 1 to 7 days) about 9 weeks; and in the severest cases 14 weeks. Eight patients were off work for 26 weeks—two on account of cerebral damage. In patients who stayed off work for an unusually long time, with the exception of the cases of cerebral damage, it could be shown that social and psychological factors were responsible rather than the physical effects of the accidents.

These results emphasize the need for prophylactic management and after-care until the patient has successfully returned to work.

My thanks are due to Prof. H. Cairns and Mr. J. C. Scott for permission to use their case material and for much helpful criticism; to Miss Horder, social worker, for her assistance in the follow-up; and to the Rockefeller Foundation for a grant to support this investigation.

E. H. Trowbridge and L. Secunda (*New Engl. J. Med.*, 1942, **226**, 195) examined the cerebrospinal fluid in 641 cases of chronic alcoholism admitted to the Boston Psychopathic Hospital between 1929 and 1939, and found that 20% had more than 45 mg. of protein per 100 c.cm. of cerebrospinal fluid. Abnormal protein in the cerebrospinal fluid was more than twice as frequent in chronic alcoholics as in controls. The presence, duration, and number of previous attacks of alcoholic psychosis had no influence on the protein of the c.s.f., and in this connexion, too, the presence of polyneuritis seemed to have no significance.

A CASE OF EVENTRATION OF THE DIAPHRAGM

BY

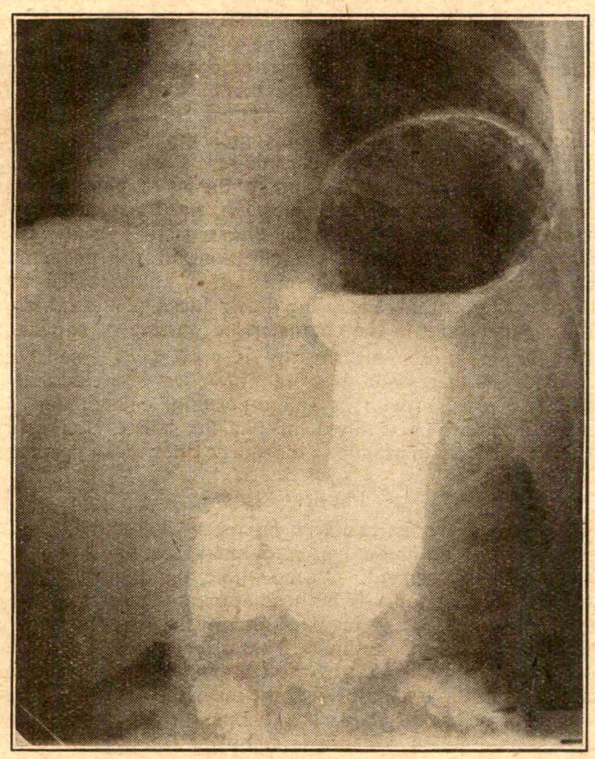
A. J. E. MILLS, M.B., Ch.B.

The condition known as eventration of the diaphragm, although rare, probably occurs more often than is generally believed. There may be no symptoms, and when symptoms are present they may be vague and misleading in character. The degree of disability resulting from the condition varies very much in individual cases. Diagnosis may not be easy. The following case is of considerable interest as illustrating these points.

Case Report

The patient, a man aged 37, is a solicitor. He was first seen by me on Nov. 18, 1941, when he was suffering from an attack of acute nasopharyngitis. A routine examination of the chest, however, revealed quite unusual physical signs, and a day or two elapsed before it was recognized that they were in no way related to his febrile illness.

On examination the thorax was seen to be of normal size and shape. Movement on respiration was diminished on the left side in the lower part. The apex beat was neither visible nor palpable in the normal position. A pulsation, which corresponded in rate to the radial pulse, was felt in the fourth interspace, 2¾ in. to the right of the midsternal line. Normal heart sounds were heard on auscultation over this pulsation. Cardiac dullness extended from 2¾ in. to the right of the midsternal line to 1 in. to the left of the midline, and downward to merge with the liver dullness. The upper border was not elicited with any accuracy. Apart from the abnormal position of the heart, the physical signs on the right side were normal.



Radiograph taken after a barium meal, showing high position of left diaphragm, marked displacement of heart to right, and large bubble of gas in stomach.

On the left side anteriorly, from the level of the fourth rib downward and round into the lowest third of the axilla, the percussion note was tympanitic. In this area the breath sounds were absent, being replaced by splashing and gurgling sounds. Posteriorly, on the left side, the percussion note was impaired from the level of the angle of the scapula downward to the extreme base, where it was again tympanitic. In these areas of impaired resonance and tympany the breath sounds were greatly diminished, the vocal resonance reduced, and the vocal fremitus absent. Elsewhere on the left side, both anteriorly and posteriorly, the percussion note was resonant, the breath sounds vesicular, and the vocal resonance and fremitus normal. The patient had no pain, but complained of a feeling of distension in the lower chest and upper abdomen on the left side.

A radiological examination was made by Dr. George Grant, who reported as follows: "The left diaphragm was much elevated into the thorax and a large collection of gas was seen immediately beneath it. The heart was much displaced to the right and gave almost an appearance of dextrocardia. Investigation on the screen showed that the left half of the diaphragm moved normally with inspiration and expiration, except that the excursion was less."

Further radiological examinations were made on Jan. 19, Feb. 16, and March 7, 1942, and all showed the position of the heart and the left diaphragm to be unchanged. "A barium meal passed down a normal oesophagus without delay and entered what appeared to be an upper loculus of the stomach, lying in the posterior half of the base of the thorax; the contents eventually 'spilled-over' into the lower main part of the stomach, which appeared normal. A lateral view showed the peculiar form of the proximal half of the stomach with much distension. The biloculation appeared to be due to inversion posteriorly of the cardiac end. There was no pyloric stenosis, and passage onwards of the meal was normal. No other abnormality was seen except for the high position of the splenic flexure."

Several clinical examinations were made at subsequent dates up to May 21, and on each occasion the physical signs described were found to be unchanged.

Apart from an attack of "threatened appendicitis" at the age of 12 years and left-sided herpes zoster at 22, the patient has had no illnesses of note. During his school and university careers he regularly took part in long-distance running and hockey, and continued to play hockey until he was 34 years old. He believes that he was always more "short of breath" than most people under the same circumstances, and was unable to play in any game earlier than 3 to 4 hours after his last meal. For as long as he can remember he has often suffered from a feeling of distension in the epigastrium and left hypochondrium. This and frequent paroxysms of severe hiccup have been his chief symptoms. An attack of hiccup often lasts for well over an hour and is only relieved by lying down for a considerable time. The appetite is fairly good, and there is no nausea, vomiting, heartburn, or water-brash. The bowels are regular, evacuation is easy, and the stools are not constipated. He is a teetotaller and a non-smoker. In Feb., 1941, he was passed as Grade I by a medical board for military service.

There can be little doubt that the case is one of eventration of the left side of the diaphragm, and almost certainly of congenital origin.

Discussion

The absence of paradoxical movement excludes the possibility that the condition is due to a paralysis of the left phrenic nerve. Singleton (1937) and Hurst (1941) claim that a diagnosis of congenital eventration of the diaphragm cannot be made in the absence of paradoxical movement. Bayne-Jones (1916), Korns (1921), and Reed and Borden (1935), on the other hand, all agree that the movement on the affected side may be normal, diminished, or paradoxical. In the 6 cases described by Wood and Wood (1931) paradoxical movement was noted in only one.

Increased divergence of the costal margin from the midline on the affected side, due to action of the intercostal muscles unopposed by the weak diaphragm, was seen in this case. This phenomenon has been referred to as Korns's sign, and was stated by Korns (1921) to be diagnostic of eventration in contrast to herniation of the diaphragm. According to Hurst (1939), megacolon is commoner than congenital defect as a cause of high position of the left diaphragm. In the present case neither the clinical findings nor the appearances during administration of a barium enema and after a barium meal were at all suggestive of megacolon. That the condition is one of *aérogastrie bloquée* is unlikely, as acute pain was never present, the clinical and radiological signs did not vary, and the passage of a tube into the stomach was without result.

Of the subjective symptoms present, hiccup was the most prominent in my case. In a search through the relevant literature I have failed to find this mentioned as a symptom of eventration of the diaphragm.

Summary

A case of congenital eventration of the left side of the diaphragm in a man aged 37 is described. Although associated

with marked displacement of the heart, he is able, with certain precautions, to undergo violent exercise, and was placed in Grade I by a medical board. Hiccup is a prominent symptom which has not hitherto been noted in connexion with this condition.

THE SIGNIFICANCE OF PLEURISY AND PLEURAL EFFUSION IN DIFFERENTIAL DIAGNOSIS

BY

R. R. TRAIL, M.C., M.D., F.R.C.P.

Wing Commander, R.A.F.V.R.
Physician, Royal Chest Hospital, London; Physician to Surgical Unit, Papworth; Consulting Physician to the Grosvenor Sanatorium

The assessment of the significance of pleurisy and pleural effusion comes under three main headings of history and physical signs, *x*-ray diagnosis, and laboratory examination of fluid in cases of frank effusion. Only by considering the findings in this order can the physician come to a justifiable decision in any difficult case for differential diagnosis. To place too much reliance on the results of the accessory laboratory and *x*-ray reports without considering them in the light of the fundamental findings of careful history and physical examination may lead to disastrous results for the patient.

History : Temperature

Certain points in the history deserve special attention. The age of the patient can often give an indication of what the physician may expect as the true cause of the condition. At all ages the possibility that the illness is secondary to any primary lesion between pneumonia and new growth must be borne in mind, but there are certain broad lines of direction. Thus, if we are to believe after-histories, the disease is seldom tuberculous under the age of 15. In the age group 15 to 25, however, the diagnosis of tuberculosis must be to the fore: while at its earlier ages many cases are idiopathic, towards its later ages we must be on the look out for underlying lung disease. The probability of such primary tuberculous disease remains in age groups up to 40; over 40, new growth demands increasing consideration.

Examination of the temperature chart can give much assistance. Tuberculous pleurisy and pleural effusion usually cause an acute rise of temperature to the neighbourhood of 102° F., and while in primary idiopathic cases the fall is commonly by steady lysis, that in secondary tuberculous effusion is by interrupted lysis—that is, in a series of peaks of temperature at intervals of 2 or 3 days, each successive peak being slightly lower than its predecessor, and intervening falls being of 1 or 2 degrees. Such a temperature chart is not like that of pleural effusion complicating the case of pneumonia. Here the initial onset temperature round 103° F. is maintained until the crisis brings a fall to a subfebrile rather even level, maintained as long as the fluid is clear, but replaced by swinging variations on the appearance of pus. It is not, however, easy to distinguish such a chart from that of pneumonia complicated by abscess of lung. The charts of effusion in new growth or cardiac and renal failure may show continued subfebrile temperatures, but most show no rise above the normal line.

Pain

The history of pleural pain, with reference to its site and intensity, is almost diagnostic in several instances. The agonizing mid-axillary pain of pneumonia is totally unlike the basal discomfort of the bronchopneumonic. That described as the "growing of wings" between the shoulder-blades, often the first sign of plastic pleurisy in a recently active case of phthisis, is quite different from both the "rheumatic" shoulder ache of healing and healed upper-zone tuberculosis, and the shooting shoulder and upper-arm "neuritis" of diaphragmatic pleurisy. The stabbing posterior axillary pain of acute tuberculous pleurisy—of longer duration than pneumonic pleurisy, and often maintained until effusion is established—should be readily distinguished from the pain of middle-lobe collapse. Here the pain is always anterior, below the mammary line, periodic, and varying in characteristic waves of intensity from discomfort to acute agony. Further, such varying intensity in a confined and usually silent area is in direct contrast with the slightness or absence of pain associated with an extensive pleural rub in abscess of the lung. On the other hand, the limited extent of pleural signs as against the marked extent of dullness in the average bronchiectasic is an interesting comparison with the repeated discomforts and absent or anomalous stethoscopic findings in cystic disease of the bronchi. Epidemic myalgia ("Bornholm disease") shows such variations, and so marked a dissociation between pain and pleural friction in the cases so labelled that it is probably not a true entity but a mixture of two separate conditions, some patients having muscular rheumatism and others abortive lung abscess; moreover, it is diagnosed at seasons when upper sinusitis and antral infections are common.

General Examination

Careful and complete physical examination should be carried out in all cases. The necessity for a general examination cannot be overstressed, for the possibility that chest symptoms and findings are secondary to abdominal disease—e.g., diaphragmatic pleurisy complicating subphrenic abscess—must ever be kept in mind.

The general appearance and facies will repay their study. The anxious look of fear predominates in the pneumonic, and while he may have a flush on one or both cheeks, which is particularly marked with the onset of complications, he never has the appealing look, the clear complexion, and the bright eye of the average tuberculous patient. This is in contradistinction to the muddiness of complexion which is a predominant feature in cases of chronic sepsis, whether the lesion be an encysted purulent effusion in the main pleural sac or in an interlobar fissure, bronchiectasis, or the purulent complications of congenital cystic disease. It appears fairly rapidly in the acute septic complications of the pneumonias such as lung abscess, but here is often accompanied by a look of excitement, absent in the drawn facies of the exhausted cardiac patient and in the characteristic wasting of carcinoma.

If pulmonary osteo-arthropathy is present its type should be noted, as there is a marked difference between that of established phthisis, with its antero-posterior enlargement, and that of sepsis which involves the phalanx laterally as well as antero-posteriorly to produce a diagnostic drumstick appearance.

Physical Signs

Two points are particularly important in actual physical signs: the position and extent of dullness, and any evidence of mediastinal displacement. On the whole, the dullness of established lobar pneumonia is both anterior and posterior, and in intensity is equal, at any involved area in the lung, between the periphery and the mediastinum. That of collapsed lower lobe is first completely posterior; as the collapse progresses, the dullness diminishes in extent towards the inner third, while the outer zones become more and more tympanitic by compensatory emphysema. When collapse is complete the dullness is confined to the anterior cardio-phrenic angle. Such a finding is in direct contradistinction to the bilateral areas of dullness confined to the costo-phrenic angles in pleural effusion complicating cardiac failure, and should not be confused with either the outer-half dullness of established tuberculous pleural effusion or the anterior lower-zone dullness of a collapsing middle lobe.

The "sterno-mastoid sign" is the easiest method of diagnosing mediastinal displacement, as tension of one muscle will demonstrate the pushing or pulling of the mediastinum to the same side as the tension. The sign is a valuable correlation with the position of the apex beat, the displacement of which means that there is a lesion on one side of the chest which is either confined to the lower zone or involves all three zones of the lung. Upper-zone disease alone seldom moves the apex beat. An actual example of the application of these findings may be given in the diagnosis of fluid complicating right-lower-lobe collapse. Immediately collapse begins, the sterno-mastoid on the same side becomes tense. As collapse increases, the apex beat moves to the right. Should fluid supervene on the collapsing lobe the position of the apex beat will not be an aid in itself; it will often remain within normal limits as the result of two opposing forces. The sterno-mastoid sign, however, remains positive on the right side and will therefore be direct evidence that the case is one of secondary and not of primary pleural effusion.

X-ray Examination

The examination of *x*-ray films of pleural effusion requires specialized knowledge. Unfortunately it has become accepted in many textbooks that the radiograph of frank pleural effusion is recognized by a curved line showing a concavity downwards and inwards from the axilla to the diaphragm. It is possible that to wait for such a confirmatory line may postpone necessary treatment and diagnostic pleural puncture to a late stage. Fluid first accumulates in the posterior diaphragmatic angle, and from the beginning seems to be associated with an area of fine equal loss of translucency in the costo-phrenic angle of the affected side. Examination of several cases seen at this early stage appears to lead to the conclusion that this shadow is at first due on the right side to a relaxation of the diaphragm and a rise of the liver. The differential diagnosis of the shadow of established effusion, as against that of pneumonia, is that while pleural effusion shows loss of translucency increasing in density from the periphery to the middle zone, the shadow of established lobar pneumonia is equal in density at any one level between the periphery and the mediastinum. Moreover, the fact that pneumonia does not displace the mediastinum is a distinct aid.

The changing density of shadow in pleural effusion is due in the majority of cases to pressure-collapse of the lung; the establishment of a definite linear curve means only that already there is some organization of the visceral pleura. The midzone density may of course be due to underlying disease of the lung. In both cases withdrawal of fluid, even if accompanied by air replacement, is not always helpful to final diagnosis, as all that may occur is that the fluid remains over the collapsed or diseased area, to produce a shadow this time convex in outline as against its previous concavity.

The case of suspected interlobar effusion should always have the benefit of a lateral radiograph, and it often pays to carry out a lordotic examination at the same time.

The main difficulties in the differential diagnosis of interlobar effusion are connected with shadows in the region of the right upper interlobar fissure. Here the physician may have to consider the possibilities of pneumonia affecting one branch of the bronchus, tuberculous pneumonia, and bronchial carcinoma. While pneumonia in its later stages of non-resolution may produce a concavity upwards of the interlobar fissure, the uncomplicated case seldom shows a well-defined line. Tuberculous pneumonia usually has its most marked density of shadow above the middle third of the raised interlobar fissure. New growth has similar increased density of the inner third. Involvement of one branch of the bronchus by pneumonia gives an inner or outer third increase of density according as to whether the infection is in the axillary or the pectoral branch; it is not confined to the interlobar fissure, but extends well into the lung substance. In all such chronic conditions the upward concavity in the interlobar fissure is due to shrinkage-collapse of the affected lobe and compensatory emphysema of the underlying lobes. An added help in the radiograph is that whereas tuberculous pneumonia from its start, and bronchial carcinoma in its later stages, show mediastinal displacement to the affected side, uncomplicated pneumonia shows a central mediastinum. Interlobar fluid, if it does cause displacement, will show it to the side opposite from the lesion until the effusion becomes encysted and, in drying, produces fibrosis. Again, where fluid is present the underlying compensatory emphysema is no longer evident: the well-defined interlobar fissure becomes a straight line or shows a convexity as against its previous concavity.

The shadow of middle-lobe collapse is so different as to be usually diagnostic, especially in the lateral view. The antero-posterior view has two specific findings. The first is that the shadows in the lower midzone are lateral in formation as against the usual downward and outward distribution of lower-lobe bronchopneumonia. The second is that there is almost always an area of translucency between the raised diaphragm and these lateral shadows. The lateral radiograph may be completely diagnostic in itself, in that it shows a typical triangular formation, the upper apex of the triangle lying at the junction of the upper two-thirds and the lower third of the mediastinum, the upper outer side of the triangle going outwards towards the fourth rib in the axilla, and the inner lower side passing downwards and inwards towards the middle of the raised diaphragm.

Difficulty is often encountered in the differential diagnosis of middle-lobe collapse or fibrosis on the one hand and mediastinal or mediastino-interlobar effusion on the other, by faulty positioning of a patient who has to be radiographed by portable apparatus while in bed. Often a semi-lordotic film is produced, giving a confused picture of the mediastinum and a squat shadow of the heart, and it may be necessary to support the patient in bed to get good antero-posterior and lordotic pictures before final diagnosis is made.

Idiopathic diaphragmatic pleurisy does not show any involvement of lung or diaphragm in radiographs. A secondary diaphragmatic pleurisy is common in abdominal disease, and in particular in subphrenic abscess. The effusion tends to be localized, and in most cases shows in the antero-posterior picture as a loss of translucency which sits above the line of the diaphragm, with a density little less than that of the underlying congested liver.

The radiograph of the transudates of cardiac and renal failure generally shows bilateral effusion, small in extent, and confined to the costo-phrenic angles.

Examination of the Fluid

It does not seem to be generally recognized that it is of primary importance to accompany the examination of pleural fluid with a complete blood count. This is as important as the general examination of the patient, as it is quite possible that an underlying primary disease, either lung or abdominal, may be missed in all good faith. For example, the finding of a predominant leucocytosis in the blood film is as important as the presence of excess polymorphs in an effusion which is going on to empyema. A diaphragmatic effusion in its early stages may be read as tuberculous in origin, whereas the true underlying condition may be subphrenic abscess.

In general, it may be stated that it does not follow that an effusion in a known tuberculous case is necessarily tuberculous; difficulties have been encountered in cases in which the true primary cause has been shown later to be cardiac failure. Another general point that requires emphasis is that no effusion should be considered as blood unless such blood is evident to the naked eye. In the examination, therefore, it is always necessary that the pathologist should compare the actual incidence of leucocytes and of true red cells in the sample submitted. Further, it does not follow because there is blood to the naked eye that the underlying condition is necessarily new growth; it may be acute tuberculosis.

The appearance of the fluid can be of much help. A clear odourless yellowish fluid is found in both exudates and transudates, but the tuberculous exudate clots more readily, has a higher specific gravity, and usually contains protein of more than 4 mg. per c.cm. Its cell count shows excess of small lymphocytes. An excess of endothelial cells is common in transudates and in obstruction to the circulation; it may suggest new growth, but is not diagnostic. Excess eosinophils are common in hydatid cyst which has been mistaken for pleural effusion. It is said that if they occur in a post-pneumonic effusion the prognosis is likely to be good, in that the patient will not go on to empyema.

The bacteriology of tuberculous fluid can be very misleading if the proper time for examination is not chosen. Fluid withdrawn at the onset of tuberculous effusion will usually be entirely negative to both culture and guinea-pig inoculation, and if this finding is taken as conclusive the result to the patient may be serious.

Cloudy fluid is common in streptococcal infections. Chylous effusion is usually opaque and must make the physician think of chronic tuberculosis or endothelioma of the pleura. It is exceedingly common in injury to the left subclavian vein or the main thoracic duct. Purulent effusions which are odourless are as a rule thin in the early stages. Tuberculous septic pyothorax usually gives a greenish-yellow purulent fluid. Where the effusion is offensive, the observer must immediately suspect the presence of lung or bowel communication with the pleural cavity, and his mind will run on a differential diagnosis for the primary lesion as between abscess of lung, bronchiectasis, empyema with broncho-pleural fistula, and pus in the abdomen, where subphrenic abscess is by far the commonest finding.

TRANSUTERINE INSUFFLATION AND SALPINGOGRAPHY

BY

A. LEECH-WILKINSON, B.M.Oxon, F.R.C.S.Ed.
Hon. Assistant Gynaecologist and Obstetrician, Royal United Hospital, Bath

The usual methods of uterine and tubal insufflation, whether by gas or by radio-opaque substances, are somewhat tedious to carry out, and their use often involves a certain amount of physical as well as psychological trauma to the patient. The following method, in which a simplified type of cannula is used, was evolved by me some twelve months ago, and has proved to be satisfactory either for gas-insufflation in the consulting-room or for injection of radio-opaque fluid in the *x*-ray department or operating theatre.

The Apparatus

The insufflation cannula (Figs. 1 and 2, B) consists of a hollow metal tube with a conical, rather sharp, screw-tip; this can be screwed into the cervical canal tightly enough to prevent leakage around it. At first sight this might seem a traumatic procedure; but repeated examinations made after its use have failed to show that any damage has been inflicted on the cervix, nor is the process of insertion and screwing-in attended with more than very minor discomfort. The proximal end of the tube is expanded so that a rubber tube can be slipped on to it from the ordinary CO_2 or air-insufflator apparatus, and into this same end can be screwed, if lipiodol is to be used, an adapter with bayonet-fitting to take any standard S.I.M.A. syringe (Fig. 1, E). The cannula also has a stylet (Figs. 1 and 2, C), which reaches about three-quarters of an inch beyond the distal end. The purpose of this is to guide the cannula into the cervical canal, from which it is automatically extruded during the process of screwing-in.

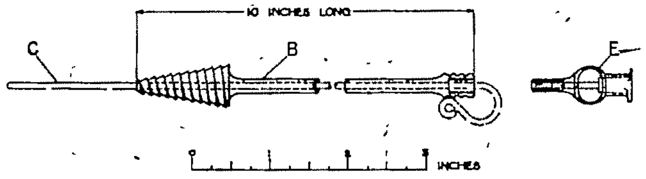

FIG. 1

Method of Use.—The patient lies in the left lateral or the lithotomy position. A narrow, warmed and lubricated Fergusson's speculum with obturator (Fig. 2, A) is passed and the obturator withdrawn. Illumination is provided by anglepoise lamp or headlamp, and when the os presents it is mopped dry and cleaned with a suitable antiseptic; for this purpose I have found it convenient to use cotton-wool swabs held in Desjardins' gall-stone forceps (Fig. 2, D). The speculum is steadied with the left hand, and the cannula, armed with its stylet, is passed with the right hand. The stylet, guiding the tip of the screw-cone through the external os into the cervical canal, is now loosened, and the cannula is screwed home gently but firmly; the stylet is now removed and the speculum may also be withdrawn. If the patient is in the left lateral position she is now asked to turn on to her back; meanwhile the cannula is simply steadied by the operator, for it will not disengage itself. The gas or lipiodol connexion is now fitted at the distal end of the cannula, and the routine insufflation carried out with the minimum of assistance and fuss.

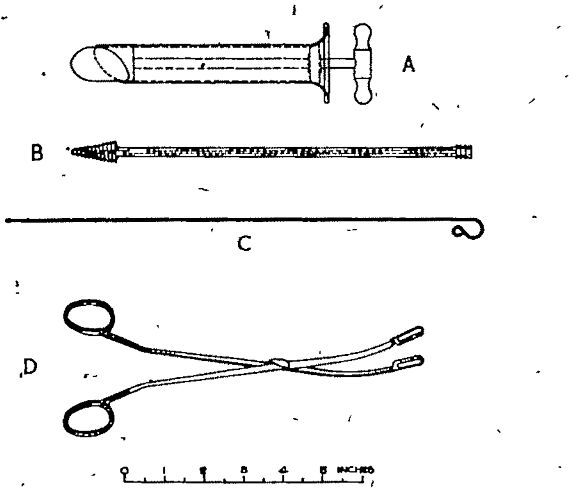

FIG. 2

Comment

1. It is claimed that this method has the merit of simplicity.
2. An air- and oil-tight connexion is ensured, and hence leakage, which may produce false impressions, is avoided.
3. The use of vulsella, which are painful and traumatic when applied to the cervix, is rendered unnecessary. This is particularly valuable, since distortion of the uterus and appendages by traction and countertraction is avoided. Indeed, the cervix can actually be pulled down during insufflation or injection, if desired.
4. During the process of "screwing home" the patient may complain of some pain; this is usually slight, and ceases as soon as the screw is fixed in the cervix.

The cannula was originally made for me by Mr. A. E. Christmas of Frome, to whom I am greatly indebted for many helpful suggestions, and is now being manufactured and marketed by Messrs. Down Bros. Ltd.

THE PITRESSIN DIAGNOSIS OF IDIOPATHIC EPILEPSY

BY

WILLIAM BLYTH, M.D., D.P.M., F.R.F.P.S.G.
Psychiatrist, E M S.

As a rule in hospital practice there is little urgency for a rapid diagnosis to be made in cases of suspected idiopathic epilepsy, and doubtful cases can be submitted to prolonged observation until an actual seizure has taken place. There are, however, certain occasions when it is necessary to establish a definite diagnosis as early as possible. In the average hospital case the required period of observation will be a matter of days or at the most a week or so, but when irregular seizures occur at infrequent intervals this period may have to be extended into months before a definite diagnosis can be established. It is with a view to curtailing this period of observation that an attempt has been made to determine a method whereby the condition can be diagnosed with a degree of certainty in the absence of seizures.

Indications for Use of the Method

The circumstances under which it may be necessary to give a rapid opinion on the existence or otherwise of this condition will, of necessity, vary according to the requirements of the individual case, but the following are indications in which the method has been found to be of value.

1. In order to differentiate between idiopathic epilepsy and hystero-epilepsy.
2. Where the existence of idiopathic epilepsy has been claimed by a patient in the absence of clinical evidence and a definite diagnosis has to be established.
3. When a diagnosis has to be made in a case where the history and clinical features are suggestive of the presence of idiopathic epilepsy, the existence of which is denied by the patient, and where a seizure has not resulted.
4. Where a diagnosis has to be established as a result of various conduct abnormalities being attributed by the patient to the existence of idiopathic epilepsy, and where a seizure has not resulted.
5. Where a differential diagnosis has to be made between idiopathic epilepsy and malingering.
6. Where, under any of the foregoing indications, there is an added urgency for legal reasons, and where time does not suffice for the usual method of continued observation by a trained nurse until an actual seizure ensues.

At present these various indications are often encountered in the routine examination and assessment of Service cases, and the importance of reducing the period of observation necessary, with the resultant economy in time, expenditure, and man-power, as well as the greater accuracy afforded in diagnosis, can be readily appreciated.

Relation of Water Balance to Idiopathic Epilepsy

The rationale of the method adopted depends upon the fact that retention of water in the body will precipitate a seizure in predisposed persons while exerting little influence on normal individuals. In 1931 McQuarrie, studying the effects of prolonged pituitary antidiuresis combined with increased fluid intake on young epileptics, found that seizures resulted in predisposed subjects but not in others. Working along similar lines, Temple Fay found that abnormalities in water metabolism were an important predisposing factor in the production of idiopathic epilepsy. Similar investigations have been carried out by Jacobsen, and later by Clegg and Thorpe, who have made exhaustive studies on the relation between the water balance of the body and the occurrence of epileptic seizures. Clinically, the frequency with which distension of the subarachnoid space is demonstrable in epileptic subjects either by means of operative procedure or by encephalography is of importance, while various observers have stressed the efficacy of hydragogue cathartics in the reduction or averting of seizures without associating this finding with the water balance of the body, but rather attributing the beneficial results obtained to the removal of toxic substances.

The establishment of a positive water balance in a selected subject can be obtained by the prolonged ingestion of copious amounts of water alone, but this method requires the expenditure of a considerable amount of time and often leads to lack of co-operation on the part of the patient and, in some cases, to actual refusal to continue to submit to investigation. More rapid results are obtained by the oral administration of copious amounts of water accompanied by pitressin intramuscularly. This is the pressor and antidiuretic principle of the posterior lobe of the pituitary, as distinct from the oxytocic. This substance has the property of causing marked water retention in normal individuals while having the subsidiary effects of stimulating the involuntary muscle of the gastro-intestinal and genito-urinary tracts and slowing the pulse.

Experiments with anaesthetized animals have shown that pitressin, even in small doses, produces a temporary polyuria followed by a reduction in output which in time amounts to an almost complete stoppage of flow. In non-anaesthetized dogs the antidiuretic effect is well marked, and this is also the predominant effect in the human subject. The action of pitressin in causing water retention in a normal subject is demonstrated in the accompanying chart. A is the normal curve, showing the accumulative excretion of urine resulting from the ingestion of 1,000 c.cm. of water at 8 a.m. The curve reaches its zenith after the expiry of 5 to 6 hours, and remains at a fairly constant level thereafter. B shows the effect produced by injections of 1 c.cm. of pitressin under similar conditions. C and D show the effect produced by injections of 2 c.cm. and 3 c.cm. of pitressin respectively. It will be seen that even in small doses this substance has a well-marked antidiuretic effect on the human subject.

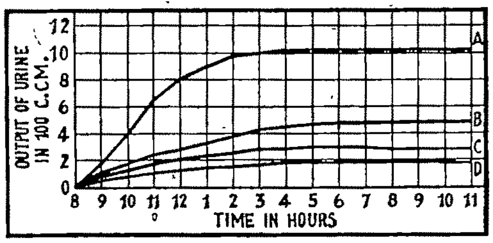

Chart showing the water-retaining action of pitressin in a normal subject.

A Preliminary Test

On account of the physiological properties of pitressin there are certain contraindications to its employment in diagnosis. These are mainly the presence of diabetes, nephritis, arteriosclerosis, and myocarditis, and before starting the investigation it is advisable to eliminate the existence of these conditions by a routine urinary examination, an estimation of the blood pressure, and a cardiovascular examination. The test adopted was carried out in the following manner.

The patient under investigation was confined to bed throughout the test. The bowels were opened by an enema, urine was voided, and his weight was then taken. Ordinary diet was maintained throughout; any previous sedative therapy was discontinued, and he was encouraged to drink copious amounts of fluids. The intake and output of fluid were charted daily, while the patient was weighed morning and evening. An increase of 2% in the body-weight with the ingestion showing an excess over the excretion was accepted as evidence that a positive water balance had been established (earlier investigators stressed the importance of there being a 3 to 6% increase, but this standard was abandoned in the early stages of the present investigation as the period necessary to obtain this additional increase defeated the purpose of the test.) The average period required for the establishment of this balance with a co-operative patient carefully supervised was 48 hours. Throughout the investigation known non-susceptible patients were used as controls. When a satisfactory water balance had been attained, 0.25 c.cm. of pitressin was injected intramuscularly and 300 c.cm. of water was administered orally. Thereafter 0.5 c.cm. of pitressin was injected and 300 c.cm. of water given orally every two hours to a total of 10 injections. On the occurrence of a seizure the treatment was immediately stopped, but otherwise the full course was given. In every case pallor followed the administration of pitressin within 5 minutes of the injection, and lasted on an average for 3 hours, disappearing after the second or third injection, but in a few cases this continued at a uniform level throughout the investigation. The physiological action of the drug was displayed by the slowing of the pulse and the tendency to looseness of the bowels, but these features were in no instance severe enough to merit termination of the investigation.

The positive evidence that idiopathic epilepsy is present depends upon the development of an actual seizure, which may be of either the major or the minor type. The failure to produce such a result does not necessarily prove that the patient is non-susceptible, and in doubtful cases the test may have to be repeated before an opinion can be given. The seizure in susceptible cases has been found to result most frequently after the fifth or sixth injection—that is, a period of 8 to 10 hours—but in certain cases this may be delayed until after the tenth or final injection, while in others a positive result may be obtained in the initial stages after the first injection.

The combination of the establishment of a positive water balance and administration of pitressin appears to be a necessary factor in the production of the seizure, as cases treated with pitressin alone without previous adjustment of the water balance failed to react, while no result was obtained in those cases in which a positive water balance alone was established. The control cases, which were previously known to be non-susceptible, displayed the physiological signs of pallor, slowness of pulse, and looseness of the bowels, but in no instance did a seizure of either type ensue. This specific action enabled the differential diagnosis between the idiopathic and hysterical types to be readily made without having recourse to a period of prolonged observation.

The above test was carried out on 87 cases in which it was desired either to establish or to eliminate the possibility of the presence of idiopathic epilepsy. The following Tables summarize the results obtained.

TABLE I.—*Results in Cases in which Presence of Idiopathic Epilepsy was Suspected from the History or Clinical Features but Existence of which was Denied by Patient*

Cases treated	49
Positive results	45
Failure to react	1
No. stopped	3
Test result verified by subsequent history	39

TABLE II.—*Results in Cases in which Presence of Idiopathic Epilepsy was claimed by Patient in Absence of Supporting Clinical Evidence*

Cases treated	38
Positive results	8
Failure to react	28
No. stopped	2
Test results verified by subsequent history	7

TABLE III.—*Results showing Position in Course of Test at which Seizure Resulted*

Cases Treated	Positive Results	No. of Pitressin Injection									
		1	2	3	4	5	6	7	8	9	10
87	53	2	1	2	4	19	17	0	0	2	6

In every case the patient was kept in hospital under observation for a period of one month after the termination of the investigation for the purpose of obtaining corroborative evidence, or until such time as a seizure resulted if this period was less than one month. In those cases in which no evidence was available at the expiry of this period the patient was discharged and the subsequent medical history was followed up through the medium of the family doctor.

The above Tables show that only 1 out of 49 susceptible cases failed to react, and that of the 45 cases which gave a positive reaction 39 (86.6%) were later found to furnish corroborative evidence of the accuracy of the test. In the second group, positive evidence was afforded by means of the test at the expiry of 72 hours in 8 cases, which would otherwise have required a prolonged period of observation; of these 8 cases 7 later furnished corroborative evidence in the light of the subsequent history. In only one case of the series did a positive water balance fail to be established and result in ending the investigation, while 2 cases had to be terminated on account of the nausea which persisted in spite of various forms of treatment. Three cases had to be terminated, on account of non-medical factors associated with home circumstances, before any definite result could be obtained.

These findings are in keeping with Jacobsen's original investigation of 40 patients, mostly children and known epileptics, in whom a seizure was induced in every case by the use of pitressin after the water balance had been satisfactorily established. Clegg and Thorpe, under similar conditions, obtained positive evidence in a group of 16 adult epileptics.

As experimental water intoxication in animals results in the onset of convulsive seizures and vomiting, and although epileptic phenomena can be more readily produced in animals than in man, it is reasonable to deduce that some relation exists between the water balance of the body and the onset of the actual seizure. The epileptic's nervous system appears to be unstable and easily influenced by minute changes in the osmotic pressure of the body fluids. As water retention is accompanied by a lowering of the osmotic pressure of the blood serum it is considered that the factor precipitating the actual seizure is the resultant exudation of fluid into the intratrabecular spaces, which are loosely supported, and that subsequent to the seizure the osmotic pressure of the blood serum returns to its normal level. The specific *modus operandi* of the antidiuretic effect of pitressin is not yet fully understood, but water elimination is probably retarded by a change in the permeability of the cell membrane and the establishment of a new balance between water loss and water concentration. Whether the precipitating factor is controlled or influenced by psychological, dietetic, allergic, endocrinic, or other factors has not as yet been ascertained, and further work along parallel lines will be required before a definite statement can be made as to the actual cause of the seizure. This finding has been claimed to be of therapeutic value by certain observers, who state that beneficial effects follow the use of a diet with a minimum fluid intake. To be effective, however, the course of treatment must be prolonged over a number of years, and this is apt to cause the patient a degree of distress, with a consequent discontinuance of the routine.

Summary and Conclusion

A method of investigation suitable for use in cases of suspected idiopathic epilepsy has been advanced. The method has been found to possess the advantage of enabling a fairly accurate opinion to be given in a short time. In the average case this period will be 72 hours, consisting of 48 hours for the establishment of a positive water balance and a maximum period of 24 hours for the actual investigation. The advantage of this in the grading of Service cases at the present time can be appreciated, while it offers certain economic advantages to hospitals and out-patient centres.

The accuracy of diagnosis as verified by a subsequent follow-up of cases has been placed at 86.6%, after a prolonged investigation of 87 unselected cases of average adult age.

The method possesses the advantage of simplicity in application and interpretation of results. The period of observation is reduced to a minimum, and the method need only be subsequently utilized in cases in which a positive result has not been obtained at the end of the period.

A suggestion as to the mode of producing the actual seizure has been advanced and further lines of investigation have been indicated.

ADDENDUM.—For some years past it has been recognized that the electro-encephalograph furnishes a ready and accurate means of diagnosing the presence of idiopathic epilepsy on account of the abnormal waves which are met with in these cases. While it is not suggested that the method outlined above should replace that of electro-encephalography, it affords an accurate gauge and may be utilized by all classes of practitioner, to many of whom the facilities afforded by the former method are not readily available.

Medical Memoranda

Diphtheria during Immunization

At the present time, when so many children are being immunized, the following case is of some interest.

CASE RECORD

A child aged 5 was inoculated with the first dose—0.2 c.cm.—of diphtheria prophylactic. She was a perfectly healthy child and had had no previous illness of any significance. The inoculation was done with the usual aseptic precautions, and the phial was well shaken in order to mix the contents thoroughly. The inoculum used was alum-precipitated toxoid (A.P.T.). This preparation was chosen because it is particularly useful in children under 8 years; it provides a high degree of immunity, and reactions from it are rare; in older children and adults reactions may be somewhat severe.

In this case, as in many others of the same age, there was no local or general reaction to the inoculation. In the third week following the first injection the patient was seen again on account of general malaise and listlessness. She was inclined to lie down and sleep, complained of a feeling of nausea, and appeared to be generally "out of sorts." On examination there were no physical signs in any system and no symptoms apart from a furred tongue; the throat was clear. The mother remarked that the child appeared to be "sickening for something," as indeed she was. She was confined to bed and given a light kind of diet and drinks, and a simple sodium bicarbonate mixture.

In two days she developed what appeared to be an acute follicular tonsillitis, with a few punctate septic spots on both tonsils. The tongue was dry and furred, she complained of thirst, and had vomited occasionally. The temperature was raised to 103.5°, the pulse was rapid, the face flushed, and she presented the usual general febrile condition. In the course of routine examination of all systems the knee-jerks (which are often absent in early diphtheria) were present. The urine was albumin-free. In the treatment advised, milk drinks were curtailed (in order to lessen the amount of methionine, which inhibits the bacteriostatic action of sulphonamides), and streptocide was prescribed—half a tablet (0.25 g.) three-hourly. The following day the patient was very much improved; she was much brighter and was sitting up in bed, the temperature had fallen to 99°, and symptoms generally had abated. The throat had cleared considerably except for a small patch on the left tonsil about 1/8 in. in diameter.

Both tonsils had been swabbed, purely as a matter of precaution; a negative swab was not anticipated owing to (*a*) the absence of a definite or suspicious membrane, (*b*) the fact that the knee-jerks were present, (*c*) the typical sharp rise of temperature suggesting an acute streptococcal throat infection. A positive result for K.L.B., however, was notified from the laboratory; by then the patient was sprightly and apparently fairly well.

COMMENT

The phenomenon of diphtheria following shortly after the first stage of immunization would lead one to consider whether administration of toxoid activates any dormant infection such as that of a carrier at the time of inoculation. One suggestion may be that there is a greater susceptibility to infection—the so-called "negative phase" following inoculation—and that a dormant bacillus, whether virulent or avirulent, may be activated indirectly or assume a comparatively virulent form in an organism of lowered resistance, producing toxic symptoms. There is thus good ground for indicating that a valuable procedure would be to swab all throats before inoculation and administer antitoxin until one obtains negative swabs—at least, in those cases in which virulence tests demonstrate a "gravis" type. Adoption of this routine would be of more value than Schick-testing, which, as suggested by Leete (*B.M.J.*, 1942, 2, 121), can be dispensed with provided one intends ultimately to immunize with a reliable antigen.

In this particular case the streptococcal infection was evidently cleared by streptocide, and it is probable that the streptococci enhanced the virulence of K.L.B. in a mixed infection.

Liverpool. G. A. GARRETT, M.B.

Removal of Filaria Worm from Eye

The following case may be rare enough in this country to merit description.

I was asked recently in the mess by a middle-aged officer who had spent a considerable period of his life in Nigeria if I knew anything about tropical diseases. Upon my saying that I had them all at my finger-tips, he asked without further preamble, "Then can you take a filaria out of my eye, Doc.?" I decided either that he was suffering from delusions brought on by too much probing into textbooks or that if he spoke the truth my assumption of knowledge had been rather too glib. However, a short examination showed a marked injection of the conjunctiva of his right eye, with a worm wriggling underneath towards the outer canthus.

We went to sick quarters, only about five minutes' walk, but by that time the worm had disappeared. It was decided to wait, and in half an hour it had come into view again in the fornix of the lower sac. The eye was cocainized, and, in the absence of ophthalmic instruments, the worm was removed with dental tweezers through a small hole made with a bistoury, the patient applying vigorous traction to the lower lid himself. He made an uninterrupted recovery from this major operation, except for some bruising of the lower lid from his own enthusiastic co-operation.

The worm was 32 mm. long on measurement. Microscopically it was identical with the textbook description of the female worm of *Loa loa*, except that the fully grown female is described as being 50 to 70 mm. long.

The history leaves little doubt that this was a *Loa loa* infestation, although the patient had been four years in this country since serving in Nigeria. Whilst there he twice had worms removed from his right eye, and once suffered from typical "Calabar swellings" on his wrist. He never suffered any other ill effects between the appearance of these worms, and had been perfectly fit since his return to this country. He does not remember the original bite, presumably by a mango-fly.

My thanks are due to Dr. Skeoch of the County Laboratory for his interest and co-operation.

Reviews

SURGICAL CARE BEFORE AND AFTER OPERATION

Surgical Care A Handbook of Pre- and Post-Operative Treatment By R. W. Raven, F.R.C.S., Major, R.A.M.C. (Pp 271. 10s. 6d.) London. Edward Arnold and Co. 1942.

Since the war began there has been almost a spate of textbooks on pre- and post-operative treatment. The most recent wanders rather widely from the course which its title might lead us to expect; thus, opening it at random, we find a micrograph of a tubercle, a reproduction of an *x*-ray film of tuberculous disease of the hip, and then four consecutive illustrations of syphilitic lesions, all of which might seem a little wide of pre- and post-operative treatment. There is, however, much useful advice on the care of surgical patients. Some of the author's statements will not be acceptable to all. It would seem a little unnecessary, perhaps even a little harsh, to prevent patients operated upon for toxic goitre from seeing any visitors for as long as three days afterwards. Some chapters are short descriptions of the subject with but brief reference to pre- and post-operative care: thus Chapter 19, on hernia, has six pages on the different varieties of hernia and their treatment, on the complications of hernia, and illustrations of trusses; and but a few lines on pre- and post-operative care relating to radical cure and to strangulation. Not only does the author of this little book skim adroitly over the field of general surgery, but he enters the specialties, with chapters on eye, ear, nose, and throat operations, on anaesthetics, and on gynaecology. The author's hope, expressed in the preface, that the book will be helpful to "all who are engaged in the management of the surgical patient, both nursing and surgical," is perhaps somewhat ambitious, as the book would appear to be too advanced for the one and perhaps rather elementary for the other, while the medical student is already well provided with handbooks of everyday surgery to use in connexion with his larger textbooks. The best and most useful chapters are those on wounds, shock, transfusion and infusion, and oxygen administration.

TWO BOOKS ON PSYCHOLOGY

Psychiatry in Medical Education. By Franklin G. Ebaugh, M.D., and Charles A. Rymer, M.D. (Pp. 619 $3.50 or 20s.) New York: The Commonwealth Fund; London. Oxford University Press 1942.

Psychology for Individual Education. By Lois Barclay Murphy, Eugene Lerner, Jane Judge, and Madeleine Grant. Edited by Esther Raushenbush (Pp 306 18s. 6d.) New York: Columbia University Press; London Oxford University Press. 1942.

These two books from America both deal with psychology but are in interesting contrast in method and purport. Prof Ebaugh and Dr. Rymer in their *Psychiatry in Medical Education* look at the subject from the professional point of view, and their study is based on a wide survey of the methods practised in many medical schools. It must be remembered that in America the word "psychiatry" includes all that was formerly grouped as medical psychology, whereas in England it is still restricted by many to the treatment of definite psychoses. The authors quote Abraham Flexner's dictum, "The medical curriculum cannot aim at producing physicians ready for practice; it can at best so train the student that experience will in time mature and equip him"—a fundamental truth that is too often forgotten in medical education. They refer to the need for some standard of selection of students suited for a medical career: a subject which will inevitably demand attention if the overcrowding of the schools continues. Moreover, at present many of these fall by the wayside, whether through disinclination or incapacity. The authors make the significant point that the teaching ability of a man is rarely considered in making appointments, and is usually unknown by his colleagues though it is accurately assessed by his students. Some courses are even given by men who themselves fail to grasp the fundamental ideas of psychiatry. As to the syllabus, they agree with H. A. Murray that academic psychology has contributed practically nothing to the knowledge of human nature and is, therefore, useless in medical education. With Prince they feel that what is wanted at the pre-clinical stage is an explanation of the mechanisms that determine mental processes.

This should come immediately after the anatomy and physiology of the nervous system; psychopathology should come at the clinical stage, just before psychiatry. The difficulty of teaching this in clinical classes is recognized because of "the danger of unwarranted intrusion on the privacy of the individual." The postgraduate training of specialists depends on the requirements of the American Board of Psychiatry and Neurology. The authors regard the dominance of the organic point of view as interfering with the recognition of the place of psychiatry in the medical curriculum. Either medicine itself must assume the burden of the teaching of psychosomatic medicine or psychiatry must focus increasing attention upon this aspect. The interrelations of psychiatry with other major divisions of the curriculum are so important that they should dominate psychiatric teaching and practice. The entire instruction might well be centred round the study of man as a whole.

Psychology for Individual Education, on the other hand, describes the course for amateurs given at the Sarah Lawrence College for Girls. Only about half the students anticipate taking up social work as such, while the remainder appear to take the course for light on their personal problems or as a subject of general culture. It is an interesting experiment, but there is the danger that it might lead only to journalistic chatter about matters of personal interest instead of to a scientific and experimental treatment of the subject. It is difficult to judge how far this danger has been avoided without having more details of what is actually taught, but it seems that the dangers were recognized by the lecturers, who were doing their best to avoid them. Thus the only male lecturer who contributes to these pages says, "It is not [the teacher's] function to probe into or attempt to treat the student's emotional problems." This does not quite harmonize, however, with the description given by another lecturer of the emotional reactions excited in the girls by the dissection of a pregnant guinea-pig. One girl, who asked for books which would help her to understand her brothers' annoying behaviour and perhaps do something about it, might have benefited from the parable of the beam and the mote, but she seems to have been dealt with wisely. However, the effect of the course on another girl was to make her "wonder whether there are people who do have good mental health." A discouraging result. No one can doubt the energy, sincerity, and conscientiousness with which these girls were psychologically vivisected, but we are left wondering whether some adolescent characteristics do not mature best away from the glare of the searchlight and the inquisitive microscope. An interesting experiment, we repeat, but one which we should hesitate to advocate in this country until there are more results on which to form a judgment.

SIR PATRICK DUN'S HOSPITAL, DUBLIN

A Short History of Sir Patrick Dun's Hospital By Thomas Gillman Moorhead, M.D., F.R.C.P.&I., LL.D. (Pp. 228. 7s. 6d. plus 6d postage) Dublin: Hodges, Figgis and Co.

The distinguished Regius Professor of Physic in the University of Dublin has never allowed any physical disability to curb his manifold activities, and so with characteristic energy he has produced a well-documented history of Sir Patrick Dun's Hospital, which is timely in view of the probable impending amalgamation with other institutions. Sir Patrick Dun was President of the Royal College of Physicians of Ireland at frequent intervals from 1681 to 1706, and accompanied William III to the Battle of the Boyne. He left his estate, subject to his widow's life interest, to the establishment of a professorship of physic, but as the estate increased in value his bequest was sequestrated for the building of a hospital, the foundation-stone of which was laid in 1803. But funds sufficient for one and ultimately for three professorships were inadequate to maintain a hospital; moreover, as it was built primarily with the object of providing clinical instruction for the students of Trinity College, it made no direct appeal to the charitable public. Thus it remained in financial difficulties until it received £176,580 from the National Sweepstakes. Even when the hospital was built its site was not attractive—on marshy land bordering a canal, which provided many intoxicated, half-drowned patients. Nevertheless, good work was done there; it was a great epoch in Dublin clinical medicine, and men such as Graves and Stokes served on its staff in earlier days, while the clinical teaching of J. M. Purser from 1874 to 1901 made a profound impression on medical thought throughout Ireland. For a short time the distinguished anatomist Alexander Macalister was on the staff. Nor must we omit reference to the work of Miss Huxley in establishing a school of nursing there.

It is unfortunate that the history of the hospital should be marred by so many quarrels, which were carried out with true Irish zest and presumably contributed more to the satisfaction of the antagonists than to the efficiency of the institution. Once again Prof. Moorhead has shown the width of his interests and sympathies, and we must thank him for this admirable footnote to the history of medical education.

Notes on Books

Dr. Geoffrey Bourne strikes the keynote of his book, *Return to Reason: An Essay in Political Diagnosis*, in the frontispiece—a diagrammatic cross-section of the brain of a gorilla and that of a man. Here we see the areas for emotional expression are almost identical, while those governing rational processes are very different. His whole plea is for cultivating the latter rather than the former, while admitting the difficulty of restricting emotional reactions to their proper sphere. Indeed, he illustrates the difficulty by his own emotional attack on politicians. That they are often too amateur in their approach to the problems they meet is unfortunately true; but many have served an apprenticeship in local affairs, and whatever their defects his conclusions are too sweeping. Nor are we impressed with his suggestion that only university graduates should be allowed to stand for Parliament; for we have known graduates who—— But we will not pursue that line of thought, merely recalling Lord Baldwin's plea that the politician's function is to tell the expert just what the public will not stand for. Nevertheless, Dr. Bourne's sincere and forcible protest against the present wave of unreason should be taken seriously: D. H. Lawrence's "dark gods," Gertrude Stein's baby chatter, much modern poetry, and surrealist painting all proclaim the triumph of feeling over reason. The disastrous consequences of this widespread attitude of mind are plain to see. If we give way to this emotional crusade the future is dark indeed. Still, it is to be feared that one is left with the trite and discouraging reflection that if men were better than they are, the world would be a better place than it is. The book is published by Hutchinson and Co. at 2s. 6d.

Gas Warfare, by Mr. W. K. Fitch, editor of the *Pharmaceutical Journal*, is offered as a monograph for instructors. It describes the characteristics of all the known war gases, their physiological effects, the necessary precautions, and the curative treatment. This little book is remarkable for the breadth and extent of the information given, covering as it does a great variety of contingencies. It is presented in a well-arranged form and is written in a commendably lucid style. The publishers are the Pharmaceutical Press, and the price is 2s. 6d.

William Clayton's *Theory of Emulsions and Their Technical Treatment* (J. and A. Churchill; 42s.) deals comprehensively with all theoretical aspects of the subject. It describes the researches of many investigations and discusses the properties of many kinds of emulsions. The new (fourth) edition incorporates important recent work, notably that of Schulman and of King Technical emulsions are treated in considerable detail, and the context is supplemented by copious references, nearly 2,000 being included in the index of authors. An interesting chapter deals with the biological aspect of the subject and describes the results of parenteral administration of fat in emulsified form. Among other observations it has been found that bacterial toxins such as those of diphtheria and tetanus lose their toxicity when adsorbed by oil globules. The book is of great practical value for the information it gives on the quality and behaviour of emulsions as well as for its excellent theoretical treatment.

War Gases: Their Identification and Decontamination, by Morris B. Jacobs, is a well-prepared handbook on gas warfare in its incidence on a civilian population. Its descriptions of war gases are especially useful to the personnel who may have to identify the gases and to estimate the extent of danger. It gives adequate data of the properties and behaviour of nearly forty gases, which include some that have not hitherto been used in warfare. Special attention is paid to the effects on food and to treatment for salving it. The book is of practical value to those whose approach to the subject is from a chemical standpoint, but it is so well written as to prove educational to others than chemists. It has been produced in New York by the Interscience Publishers, Inc., and is published in London at 18s. by the Imperia Book Company.

PERNICIOUS ANAEMIA OF PREGNANCY

It has been appreciated for nearly 30 years that a severe macrocytic type of anaemia occurs rather frequently in pregnant women in India. A recent article by Mudaliar and Menon[1] gives a good account of the disease. Anaemia of all forms is unduly common in pregnant women in Madras; over 70% of them are anaemic by Western European standards. Macrocytic anaemia of pregnancy is actually more frequent there than pre-eclamptic toxaemia, and 103 cases were found in 1,200 admissions to the ante-natal wards. It manifests itself in the second or third trimester, and the presenting symptoms are oedema, dyspnoea, diarrhoea, heartburn, nausea, and vomiting. Labour is often premature and precipitate, and the gross maternal mortality is approximately 25%. The anaemia may be profound, and haemoglobin values ranged from 50% to less than 10%. By definition the anaemia in Mudaliar and Menon's cases was *macrocytic*—i.e., the mean volume of the red cells in all the women was above 85 cu. microns. Nevertheless, in nearly one-third the colour index was below unity, even as low as 0.5, which means that, though the red cells were always larger than normal, they were often incompletely filled with haemoglobin. In the shorthand of haematology the anaemia in this subgroup was *macrocytic hypochromic*, and by inference due to shortage of both P.A. factor and iron. Megaloblasts were always present in plenty in the blood films. Complete achlorhydria was unusual, and the diet differed in no way from that of the normal Madras woman admitted for confinement. Malaria and kala-azar were not aetiological factors, but hookworm infestation was a dangerous and not uncommon complication. Recovery is complete, but relapse may occur in subsequent confinements. The risk is not great, and is an admonition to supervision and not suspension of further pregnancies. In treatment marmite was disappointing, but good results were obtained with liver given parenterally. In exceptional cases the anaemia may not respond to liver therapy before delivery, and transfusion should then be employed in addition.

So long as search was confined to cases with a peripheral blood picture identical with that of Addison's anaemia, pernicious anaemia of pregnancy remained a haematological curiosity in Western Europe and the U.S.A. But macrocytosis is only one feature of the haematology of the anaemias due to deficiency of the P.A. factor. More pathognomonic characters are the presence of megaloblasts in the peripheral blood smear along with megaloblastic degeneration of the bone marrow, and the therapeutic response to treatment by liver. The rather sharp controversy in our correspondence columns[2] over the definition of the megaloblast may have shaken the faith of our readers in the second of these criteria, but this would be to misunderstand the point at issue. Classical teaching is that the megaloblast is a cell which is found only in foetal life and in anaemias due to lack of P.A. factor, and which is incapable of developing into a normoblast and normal red cell. An American view, which was popularized in this country by Witts in his Goulstonian lectures,[3] is that the megaloblast is a normal phase of erythropoiesis, of which fleeting glimpses may be seen in health and more concrete evidence whenever blood formation is much accelerated. For a time the tide of opinion turned back to the classical view, but it has been reversed again as a result of a study by Davidson, Davis, and Innes[4] of the changes produced in the bone marrow by liver treatment. All this, though of much theoretical interest, is of little importance in clinical work. Every haematologist agrees that the bone marrow in severe anaemias due to lack of P.A. factor shows an unmistakable picture, and a mere glance down the microscope is often enough to make the diagnosis.

Armed with their two powerful new weapons—the sternal puncture needle and the ampoule of liver extract—haematologists have infiltrated into the obstetric wards in the last few years and have shown that pernicious anaemia of pregnancy, though still very much less important than iron deficiency, is more prevalent in temperate climates than had been realized. At the meeting of the Association of Physicians this year[5] Fullerton reported 3 cases from Aberdeen and Sheila Callender 23 from Dundee. Subsequently Davidson's[6] group has reported 16 from Edinburgh, Lescher[7] 17 from Derby, and Miller and Studdert[8] 23 from Newcastle-upon-Tyne. Segerdahl[9] notes that 21 cases have been recorded in Sweden since 1938. It is probable that this sudden eruption of cases is due to improved diagnosis and not to increased incidence.

A few further details about the disease may be brought together from these papers. What was the diagnosis of these cases before we learnt to recognize them as pernicious anaemia?—sometimes toxaemia, but usually puerperal sepsis, on account of the high fever which may be present. Quite frequently symptoms do not draw attention to the illness until the puerperium. It is important that the pendulum should not swing to the other extreme, for pernicious anaemia of pregnancy still remains one of the least frequent causes of anaemia in pregnancy and the puerperium. Although the colour index may be low, the red cells are rarely of smaller size than normal. The haematocrit should therefore always be used to determine the cell volume. Sternal puncture is very desirable, but it demands the help of a skilled haematologist, for the marrow picture is more mature and the megaloblasts less numerous than in pernicious anaemia. The serum iron may also prove to be a diagnostic help, though there are not many centres in this country able to estimate it. It is important to remember that women with true Addison's anaemia may become pregnant, and that Addison's anaemia may begin during pregnancy. Patients must therefore be kept under supervision after confinement to exclude this possibility, though it can be more or less ruled out by a normal test meal. Subacute combined degeneration never occurs in pernicious anaemia of pregnancy, and the child is normal. Treatment must be far more intensive than in Addison's anaemia, particularly before the baby is born; iron is often needed as well as liver, and there should be no hesitation to transfuse blood. Crude intramuscular extracts of liver are said to be more effective than highly purified extracts, and whole liver by mouth is said sometimes to be more effective than parenteral treatment; but neither of these statements is supported by really convincing evidence. Lescher divided his cases into a pernicious type which responded to liver and a haemolytic type which responded to transfusion, but it is doubtful whether any such antithesis is at present justifiable, for anaemias due to lack of P.A. factor often show a strong haemolytic component. Aetiological factors cannot be discussed now, except to hint that some authors seem to forget that the one constant element in the disease is pregnancy. Pregnancy is a time of considerable endocrine disturbance, and it is known that pernicious anaemia is unduly frequent in thyroid and pituitary disorders.[10] Diet is undoubtedly important, but in pernicious anaemia of pregnancy, as in hookworm disease and idiopathic hypochromic anaemia, diet sets the scale of frequency of the anaemia in the community rather than determines its incidence in a particular individual.

CONTROL OF BACILLARY DYSENTERY

Two recent procedures in the isolation of dysentery bacilli have enabled Hardy, Watt, and de Capito[11] to make surveys of their incidence and persistence in individuals and in communities. The first is the introduction of improved selective media: desoxycholate citrate and Shigella–Salmonella agar. The second is the use of the rectal swab, which permits fresh uncontaminated specimens to be obtained at determined intervals and to be inoculated on culture media without delay. While previously carriers of dysentery bacilli were detected rarely, they are now discovered frequently and with relative ease. Using these new methods, Hardy, Watt, and de Capito made surveys of great epidemiological interest among normal population groups, contacts of dysentery patients, and convalescent carriers. Among groups of persons without a history of diarrhoeal disorder in the past year the incidence of dysentery bacilli varied from 3.8% in New Mexico, Georgia, and Puerto Rico to 0.1% in New York City. The authors do not state, however, whether they surveyed comparable social groups. In institutions for the feeble-minded the incidence fluctuated periodically between 0 and 22%. Family contacts of recognized cases had particularly high carrier rates—e.g., 28% in New Mexico. In a military unit with endemic diarrhoeal disease 10% of the men "on duty and officially well" were found to be harbouring dysentery bacilli. The authors followed up 103 dysentery patients with routine weekly stools and found among them 80% convalescent carriers. The duration of the carrier state was on an average 34 days, and was thus six times that of the acute stage of the illness. In another infected group 10% of the patients remained carriers for more than 10 weeks.

Evidently the recent improvements in laboratory technique are revealing that convalescent dysentery carriers occur more frequently than was previously supposed, and that they may continue to disseminate infection for days, weeks, or even months after the acute illness. New, too, is the knowledge that symptomless carriers often greatly exceed in number the currently occurring cases. These facts probably explain to a large degree the prevalence of endemic dysentery in this country and necessitate a review of the epidemiology of this disease and of its control. By bacteriological investigation carriers may be sought for among cases and intimate contacts in home, institution, or military unit. But hospital isolation until bacteriological recovery occurs spontaneously is difficult owing to the numbers involved, though it is essential for special groups—e.g., Sonne dysentery cases and carriers from nursery schools or infant homes. Hardy, Watt, and de Capito have shown that treatment with sulphaguanidine simplifies the control of Flexner and Newcastle infections, which in carriers as well as cases can be terminated promptly by its use. Among two groups of untreated controls and treated alternates, all were carriers of these organisms at the outset of their experiment. At the end of ten days 76% of the untreated and only 4% of the treated were positive, and on the following day all of the treated were negative. In addition there was a striking and rapid reduction in the number of colonies even before the individual became negative. Mass chemotherapy gives, therefore, promising results for the eradication of Flexner and Newcastle dysentery in heavily infected institutions, military units, and households. The position with regard to Sonne dysentery is not so clear-cut and the authors prefer to draw no definite conclusions from their small series.

The Emergency Public Health Laboratory at Oxford[12] reports that of 11 cases of Sonne dysentery from an outbreak among young children, all of whom were treated with sulphaguanidine, 9 became negative in 0 to 9 days, and 2 in 10 to 19 days. Of 10 symptomless excreters, also treated, 9 became negative in 0 to 9 days, and 1 in 36 days. The duration of excretion was less than that found by Hobbs and Allison[13] of the Cardiff Emergency Public Health Laboratory in cases that received no treatment with sulphaguanidine. The remaining two of the Oxford patients continued to excrete *Bact. sonnei* intermittently for two months and for more than three months respectively, though the latter patient had, in all, three courses of sulphaguanidine. There was no apparent source of reinfection. The work at Oxford raises the important question of the duration of isolation required before the safe release of a Sonne dysentery patient. Since the patients in this outbreak came from a residential nursery for young children and infants, it was essential to take no risks and to have a high standard of bacteriological recovery. At first children were returned from the isolation hospital to the nursery after three consecutive negative stools and were there quarantined for a further period of three weeks. On subsequent examinations after return it was discovered that 1 of the 10 children had a positive stool. The criterion of discharge from the isolation hospital had therefore to be altered, and thereafter 8 consecutive negative stools in 4 weeks, or at least 6 negatives in 6 weeks, were required. This 4- to 6-week period of hospitalization for both cases and symptomless excreters was felt to be necessary for the exclusion of further infection from the nursery. Indeed this view was justified by the finding on 5 occasions of a positive result after 3 or more negative stools. The investigators consider that further work is necessary on the intervals and number of negative results required before terminating isolation. For the elimination of Sonne dysentery in institutions it seems that a standard of negativity more stringent than prevails at present must be adopted before the return of convalescent patients and of symptomless excreters to the community.

ANTISEPTIC TREATMENT OF WOUNDS

The revival of belief in antiseptics, given its first impetus by the success of local sulphonamide treatment and accelerated by the discovery of gramicidin and the rediscovery of penicillin, has now passed a further stage. This is a rediscovery of the possibilities of an antiseptic which has been available for a quarter of a century. According to G. A. G. Mitchell and G. A. H. Buttle,[14] whose patients were casualties from Libya, proflavine powder introduced into intractably suppurating wounds often has a dramatic effect in drying them up and promoting rapid healing, with a marked improvement in the general condition. They treated 80 cases in this way, using from 0.5 to 2 g. of the powder according to the size of the wound, and in only 6 was it apparently quite ineffective. In only one was there any suggestion that healing had been delayed by the treatment. Proflavine acts on all bacteria found in suppurating wounds, although *Proteus* is the most resistant to it; it is particularly valuable in dealing with staphylococcal infections, because these resist other treatment. Many of these cases had had full courses of systemic as well as local chemotherapy, sulphathiazole and sulphanilamide being used, with no benefit, before proflavine treatment was begun. A small amount of proflavine (0.25 g.) has also been used as a mixture with sulphanilamide (2 to 5 g.) for prophylaxis, but no actual evidence for the efficacy of this proceeding is offered. The authors appear to consider that sulphanilamide, on account of its known harmlessness to tissues, should be the mainstay for prophylactic use.

Antiseptics have been used as a matter of course for the treatment of infected wounds ever since the time of Lister, but rarely with any striking effect and usually with little expectation of it. To suggest that any recognized antiseptic of some standing can actually terminate infection in a wound within a few days is almost revolutionary. This is in fact a much more striking achievement than the mere prevention of infection in a wound where tissue invasion has yet to begin. It is worth while to examine the causes of this success. The flavines and related compounds stand alone in having been shown experimentally to be capable of preventing wound infections. They are highly, although slowly, bactericidal, and comparatively innocuous to tissues; the degree of their toxicity for leucocytes was the subject of what is now a historic controversy, but, whatever the truth on this specific point, it is at least undeniable that they can be applied to a surface or even injected interstitially without causing evident damage. Reconsideration of their properties in recent years has pointed to proflavine as preferable to acriflavine, and the studies of Russell and Falconer,[15] who showed that an isotonic solution of proflavine buffered to a reaction near neutrality could be applied even to the brain without causing more damage than that inflicted by normal saline, did much to rehabilitate this antiseptic in general estimation. Hawking[16] found experimentally that it prevented anaerobic wound infection with at least as much certainty as the sulphonamides, but discounted these effects in view of the mediocre results obtained with acridine compounds in the last war. As was pointed out in this *Journal*, to deny the significance of controlled experiment by adducing uncontrolled clinical evidence obtained under bad conditions many years earlier is questionable logic: Hawking's findings were rather an indication that proflavine should be given a further and better-conducted clinical trial. Granted that proflavine is, among the older antiseptics, possibly the best of its kind, and theoretically capable at least of preventing wound infection without doing undue tissue damage, it remains to be explained why it now appears to have achieved a success such as has never been claimed for it before. The probable explanation of this is the simple fact that for the first time it has been applied, as sulphonamides have always been applied, in solid form. Its solubility is about 1 in 300—almost ideal for persistence of effect combined with adequate concentration. Much antiseptic treatment in the past has probably been ineffective owing to misapplication; neither irrigation with a solution nor the application of a dressing soaked in it can secure the penetration and persistence afforded by a slowly dissolving solid. Treatment with proflavine powder will doubtless be extensively tried, and final judgment on its merits for various purposes will be awaited with interest. Proflavine also performed well in a study now reported by J. McIntosh and F. R. Selbie[17] of the capacity of several antiseptics for inhibiting the development of *Cl. welchii* infection in mice. It was decidedly more effective than sulphanilamide, and inferior only to penicillin. Zinc peroxide was moderately effective if applied at once, and comparison with zinc oxide and with a preparation yielding hydrogen peroxide indicated that zinc itself rather than oxygen is responsible for its effect. Gramicidin had little if any influence on the infection, in spite of its enormous capacity for preventing the growth of *Cl. welchii in vitro*. These facts will be a valuable guide in framing any new policy for preventive application to wounds. On present information there seems to be a strong case for the trial of proflavine powder for this purpose.

OESTROGEN TREATMENT OF DIABETES

The relatively high incidence of diabetes mellitus in women at the menopause is quite possibly connected with a hyperactivity of the pituitary gland, which is then no longer inhibited by gonadal secretions. This view is logical enough to suggest that treatment with oestrogens or androgens in doses adequate to depress pituitary function might do good. A further reason for the use of oestrogens lies in their capacity to increase the insulin content of the pancreas,[18] lead to hypertrophy[19] of the pancreatic islets, and stimulate their secretory activity.[20] In theory, therefore, such treatment has much to recommend it; in practice the results have been conflicting. Animal experiments at first suggested that oestrogen injections diminished the intensity of the diabetic state in depancreatized dogs[21] and monkeys.[22] These results led to clinical trials, and alleviation of diabetes in menopausal women injected with oestrogen was claimed by Gessler and his colleagues,[23] by Spiegelman,[24] and by Cantilo.[25] Saurer[26] also reports a fall in the fasting blood-sugar level and a depression of the glucose-tolerance curve (whether the glucose was given orally or intravenously) in menopausal diabetic patients given large doses of oestrone or testosterone. All these clinicians have, however, used natural oestrogens or androgens; they find that big doses are necessary, and attribute any success to a depression of hypophyseal function. The substances were injected, and there was in general a recurrence of the full pre-treatment symptoms when the injections were stopped. The treatment therefore has no advantage in comfort over insulin treatment, and it is presumably better to inject insulin, which has a specific action, than to inject unphysiological amounts of the sex hormones, which depress other hypophyseal secretions besides the diabetogenic one. However, there appeared to be little doubt that the theory behind the use of oestrogen had received practical confirmation.

With the discovery of the orally active synthetic oestrogens the subject was reopened. If orally administered stilboestrol could replace insulin injections it would be a great advantage to the patient's comfort and pocket The first report on the use of stilboestrol[27] dealt with 4 cases, of which only 2 were treated orally. One of these was given 5 mg. daily for 6 weeks, which eliminated the need for insulin and reduced the blood sugar from 180 mg. to 123 mg. per 100 c.cm., but glycosuria persisted, the other patient was kept symptom-free by daily doses of 3 to 15 mg. for 3 months. Unfortunately later results have not been encouraging and have cast some doubt on the whole question of the value of oestrogens in post-menopausal diabetes. First, Young[28] tried the effect of stilboestrol and oestrone on pituitary-diabetic and depancreatized dogs. Both substances were given by subcutaneous injection and by subcutaneous implantation of tablets, but in neither case did Young find evidence of any benefit, in spite of the fact that he was using doses very much greater than those used by the American workers.[21 22] Lawrence and Madder[29] at the same time failed to demonstrate any effects of doses of 1 mg. of stilboestrol given 4 times daily for a period of 8 weeks to 5 diabetic women aged 42 to 52. Again, Salmon and his colleagues[30] implanted stilboestrol tablets into 18 menopausal diabetic women and found an improvement in insulin requirement and glucose tolerance in only one. Thus the value of oestrogens in the treatment of post-menopausal diabetes is by no means so clear-cut in practice as it is in theory.

TREATMENT OF ISCHAEMIC CONTRACTURE

Volkmann's ischaemic contracture was originally thought to be due to circulatory obstruction resulting from the over-tight splinting or bandaging of fractures in the region of the elbow-joint. This theory was upset by the clinical evidence, however, because many cases were reported in which neither splints nor bandages had been applied. So the more modern version of the mechanical obstruction theory was propounded. This supposed the obstruction to be due to internal pressure from a subfascial effusion or haematoma in the antecubital fossa, and to be venous rather than arterial. Brooks[31] showed experimentally, as later did Middleton,[32] that if the entire venous drainage from a muscle were ligated the muscle developed a contracture. This they regarded as being identical with Volkmann's, but Griffiths[33] demonstrated conclusively that the histology of the two conditions was entirely different, and in the same paper produced further evidence against the venous occlusion theory by recording three cases which followed arterial embolism—in other words, cases in which the venous system was completely unaffected.

What, then, is the essential pathology of Volkmann's contracture? According to Griffiths—and his clinical and experimental evidence is most convincing—it is due to segmental spasm of the main artery to a limb, accompanied by reflex spasm of the collateral circulation. If the main artery alone is occluded and the collateral circulation functions, then no ill effects are observed. If the collaterals go into reflex spasm, however, the result is either gangrene or Volkmann's contracture according to whether the spasm is complete or incomplete. Foisie,[34] reviewing the early operative findings in 30 cases reported from many sources during the last two years, points to their striking similarity. In all, the lower end of the brachial artery was reduced by spasm to a string-like structure in which pulsation had ceased. Barnes and Trueta[35] have now brought forward additional experimental evidence in support of the earlier work of Griffiths. By applying a wire tourniquet for four hours they were able to produce a persisting spasm of the femoral artery in rabbits, and showed by arteriographic studies that the collateral circulation was also in spasm. They further found that the spasm of the collaterals could be abolished by lumbar sympathectomy, though the main vessel remained in spasm, and that in the rabbits in which the collateral circulation was not released in this way changes occurred in the muscles identical with those seen in Volkmann's contracture.

It is obvious, therefore, that the crucial factor is the reflex spasm of the collateral circulation. It seems established that the impulses causing this spasm originate in the walls of the occluded main vessel, but their subsequent path has not been precisely determined. They travel by way of the sympathetic system, but in human beings, at all events, they do not seem always to be relayed through the paravertebral ganglia. Successful blocking of the stellate ganglion, as evidenced by the development of a typical Horner syndrome, has failed to release the collateral circulation,[36] so there must be a more peripheral reflex path The most certain method yet known of abolishing the reflex is to interrupt it at the source by resecting the segment of main artery in spasm, a procedure originally proposed by Leriche. This operation (arteriectomy) has proved reliable in all the published cases and is the one of choice, but it must not be delayed too long. Tight plasters or bandages, or overflexion of the elbow-joint, are factors that cause additional circulatory embarrassment and should be removed. Moreover in some cases, notably in gunshot wounds in which the damage is confined to the soft tissues, the reflex spasm of the collaterals may pass off spontaneously. But faced with the possibility of such a severely crippling condition as Volkmann's contracture the surgeon should not wait long now that he has this valuable weapon to hand.

THE HEAVIEST WOMAN

If the late Mrs. Ruth G. Pontico, of Tampa, Florida, was not the heaviest woman in proportion to her height that the world has yet seen, her record can seldom have been exceeded. Willoughby,[37] who has described the case in detail, states that fewer than twenty instances of weight exceeding 700 lb. are to be discovered in the literature, even if those of questionable authenticity are included. But, whereas most of these people were tall, Mrs. Pontico was only 5 ft. 5½ in. in height; yet in 1939, at the age of 35, she weighed 772½ lb., or more than 55 stone, and may well have exceeded 800 lb. before her death two and a half years later. Her chest measurement was 81½ in., her waist 76½, and her hips 91. Incidentally Willoughby discloses a curious source of error which has sometimes given these giants of girth an extra 100 lb. or so to which they were not entitled, for the weights taken after death occasionally included the coffin, a fact explained in the original record but carelessly omitted by later historians. Mrs. Pontico owed much of her professional success—for naturally she was a "fat lady"—to the fact that she had parents of the right sort. Her mother, a member of the same profession, tipped the scale at 720 lb. and was 6 ft high. Her father was also 6 ft. high and weighed a mere 250 lb. Their daughter is said to have begun her gargantuan career by weighing 16 lb. at birth; at 1 year she weighed 50 lb.; at 10 years she touched the 300 mark. It might be thought that to manœuvre such mass freely would be difficult. But she climbed to the second floor of her home once or twice a day, and every few days was able, with rests, to walk round her extensive grounds. She took about half as much food again as a normal person. When 29 she survived an attack of pneumonia, though it took her a year to regain her health and the 200 lb. which she lost. Death followed an operation for the removal of a fatty tumour.

Nova et Vetera

FOLK-LORE OF THE ACUTE EXANTHEMATA

In a paper read before the Section of the History of Medicine of the Royal Society of Medicine, Dr. J. D. Rolleston said that in contrast with some diseases, particularly whooping-cough, pulmonary tuberculosis, skin diseases, warts, and eye diseases, the folk-lore of the eruptive fevers was somewhat scanty, though rich enough to justify a special communication. The amount of folk-lore connected with each exanthem was in direct relation, he said, to the antiquity and importance of the disease, so that in this respect small-pox, measles, scarlet fever, and chicken-pox were represented in the order named. There did not seem to be any folk-lore connected with German measles, which did not receive general recognition as an independent disease until after the International Congress of Medicine held in London in 1881. Dr. Rolleston made the following remarks on the folk-lore of the acute exanthemata as a group before dealing with the individual diseases separately.

With regard to causation, there did not appear to be any popular causes suggested for their occurrence, such as catching cold, sexual excess, or punishment for an evil life, as in the case of pulmonary tuberculosis, skin diseases, and venereal diseases. With the exception of small-pox, none of them had been assigned a Divine origin. In accordance with medical folk-lore generally, prophylaxis was rarely employed in the acute exanthemata except small-pox. There were many examples of the same treatment being applied to the acute exanthemata in general, such as overheating the patient or flagellation with nettles with the object of bringing out the rash, the use of red blankets and bed-hangings, and coprotherapy.

With regard to the causation of small-pox, Sir James Frazer and others gave numerous examples of outbreaks of small-pox in different parts of the world being attributed to a goddess or, much more rarely, to a god, and of the various means employed to win their favour or prevent their visitation. Examples were given, too, of the avoidance of calling the deity and the disease by their proper name, and of using instead some more or less euphemistic words or phrases. The supposed transfer of small-pox to animals, plants, and inanimate objects in accordance with folk-lore practice in other diseases was also described. Prophylaxis of small-pox by inoculation was a folk-lore method carried out by old women in Turkey long before it was adopted by the medical profession in England and France. Besides overheating the patient, the folk-lore treatment of small-pox consisted mainly of animal and plant remedies and the invocation of patron saints.

A greater number of popular errors were connected with measles than with any of the other acute exanthemata, such as the belief that it was a trivial disease, that it cleaned out the system and made the child less liable to contract other diseases, and that patients should not be washed owing to the delusion that such an act tended to drive the rash inwards. In none of the acute exanthemata was coprotherapy more often employed than in measles, especially in the early stage of the disease. There were several examples of the belief that measles could be best treated by transfer of the disease to animals and plants, and, apart from any idea of transfer, numerous folk-lore remedies were supplied by animals, plants, and minerals.

Doubtless because scarlet fever had been isolated as an independent disease much later than small-pox and measles, its folk-lore was much less than that of the other two diseases. Popular errors connected with it included the view that the term "scarlatina" meant a mild form of the disease, that second attacks did not occur, and that a mild attack could transmit only a mild attack to another person. Instances were occasionally met with in which scarlet fever was supposed to be transferred to animals, such as the dog, bear, or sheep. Amulets were sometimes worn for prevention of the disease. There did not appear to be any patron saints connected with scarlet fever as in small-pox and measles.

Although chicken-pox was probably as old as small-pox, owing to its usually mild character and uncomplicated recovery very little folk-lore had gathered round this exanthem, but it had had a large number of popular synonyms which were out of proportion to its real significance. The term "chicken-pox" was first used in medical literature in 1694 by Richard Morton, who spoke of a form of small-pox "called in the vernacular the Chicken-pox." Fuller also, in 1730 in a paragraph in his *Exanthematologia,* wrote: "I have adventur'd to think that this is that which among our women goeth by the name of Chickenpox."

Another example of folk-lore anticipating scientific medicine is furnished by the fact, recently mentioned by W. N. Pickles, that the connexion between herpes zoster and chicken-pox had been known at Aysgarth, in Yorkshire, long before this was demonstrated by Bokay in 1892.

GUESTS OF ST. DUNSTAN'S

Before the war arrangements were made for members of the Canadian Forces suffering serious eye injury in any European theatre of war to receive treatment at St. Dunstan's and at its training centre; this arrangement has now been extended to the U.S. Army. At a luncheon recently given by St. Dunstan's to senior officers of the American and Canadian Army Medical Services, Mr. Ernest Brown, Minister of Health, recalled that in the early days of the war a number of American doctors came to this country at their own expense and without remuneration to help at our general and special hospitals. When the U.S. Forces began to arrive it was arranged that any members of the American Services needing treatment should be accommodated in E.M.S. hospitals. In addition the Ministry of Health had handed over 5 new hospitals, fully equipped, to them, while the Canadian Forces had the use of 8 hospitals. Sir Ian Fraser, who presided at the luncheon, said that in this war, owing, presumably, to the increased use of armour in tanks and planes, fewer men were blinded by metal fragments than in the last war. A larger proportion, however, were blinded by concussion changes in the eye, causing collapse or irreparable damage through haemorrhage. Approximately two hundred and eighty-eight cases had come under the care of St. Dunstan's in this war; 88 of the patients had recovered some useful eyesight, but 200 would not recover their sight at all. Of these 200, half were in training or had been trained at St. Dunstan's in England and 30 were prisoners of war. He estimated that there would be 40 cases out of the recent fighting in Africa. It had been arranged that all American soldiers who might be temporarily or permanently blinded should be sent to St. Dunstan's for 3 to 6 weeks while waiting to return home; the first American guest was due to be admitted the following day. Brig.-Gen. Paul Hawley, chief surgeon of the U.S. Army in the European theatre of operations, said that the great shock to the blinded American soldier would come when he returned home handicapped and helpless to his family. Now he would be able to return after his St. Dunstan's training walking with confidence and facing the world with courage.

HEALTH ON THE HOARDINGS

Dr. Johnson declared that the full tide of human existence is at Charing Cross, and here there has lately been arranged, in the entrance hall of the underground station, a health exhibition under the patronage of the Ministry of Health. It is announced as an exhibition of photographs, but it is even more an exhibition of placards and posters, and some of the cartoons and slogans are not only pointed but amusing, which is a very good propagandist approach. Simple rules for fitness, condensed advice on maternity and child welfare, instruction on the dangers of contaminated food and of droplet infection are conveyed in such a way as to catch the eye of the most hurried traveller. The only disadvantage is the restricted space. Mr. Ernest Brown, at the opening ceremony, remarked on the steadily growing co-operation of the public with the health authorities, a co-operation which has been accelerated during the war. One of the results of the awakened health conscience in Great Britain, he said, was that the nation went into this war fitter than into the war of 1914, and now in the fourth year of hostilities the value of the careful work of the last quarter of a century was becoming fully revealed. Sir William Beveridge, said Mr. Brown, made three assumptions as the basis of a satisfactory system of social security, and one of them was a comprehensive service not only for the cure but for the prevention of disease, the others being family allowances and avoidance of mass unemployment. But the awakening is still far from complete, as is shown by the number of parents who neglect the facilities for immunizing their children against diphtheria, and also the facts revealed by an investigation of a cross-section of the public in which the investigators have reported to the Ministry that large numbers of people are "stumped" by the question as to where they should go for advice on the prevention of illness. Incidentally, the Minister gave a word of hearty praise to the work of the Central Council for Health Education and its chairman, Dr. Charles Hill.

IMPROVED ARRANGEMENTS FOR THE TREATMENT OF TUBERCULOSIS

Speaking in the House of Commons on October 8 the Minister of Health, Mr. Ernest Brown, stated that he had already acted on a number of the recommendations of the M.R.C. Committee on Tuberculosis in Wartime (*Journal*, Oct. 10, p. 436), and a circular (No. 2741) now issued to local authorities provides some further information. First, a limited number of portable sets for mass miniature radiography (in the House of Commons the number 30 was mentioned) are to be allocated to certain named county and county borough councils, delivery to begin early in 1943 and to be completed during the year. Secondly, arrangements are being made by the Ministry for training the necessary technical staff to operate this equipment, and this will be the subject of a later communication to local authorities. Thirdly, additional hospital beds are to be freed for the treatment of tuberculous patients, and steps are being taken, in conjunction with the Ministry of Labour, to provide further domestic and nursing staff. On the important recommendation of the committee that there should be special financial provision for those undergoing treatment, the circular says that the Ministry and representatives of local authorities are already working out a scheme of uniform assistance for all those who suffer loss or reduction of income while undergoing treatment and who have one or more persons dependent on them. The assistance will normally take the form of maintenance allowances for the patient and his dependants, and should also be available towards meeting reasonable obligations, in excess of a prescribed figure, incurred for rent and rates, building society contribution, insurance policies, and the education of children. The tuberculosis authority will usually administer these allowances. No charge should be made for the cost of institutional treatment, and, finally, local authorities will be reimbursed for expenditure incurred in the payment of these allowances. Particulars of the scheme will be circulated later.

Correspondence

Byssinosis

SIR,—May I call attention to the statement, which may give rise to some misunderstanding, in your leading article on byssinosis and bagassosis (Jan. 9, p. 46), that byssinosis is scheduled under the Workmen's Compensation Act? Owing to the special features of the disease it was not considered appropriate to schedule it in the ordinary way, but it was dealt with by a special scheme made under the powers obtained in the Workmen's Compensation and Benefit (Byssinosis) Act, 1940.—I am, etc.,

S. A. HENRY,
H.M. Medical Inspector of Factories

London, S.W.1.

Sick Absence among Munition Workers

SIR,—While agreeing with the opening paragraph of the article by Drs. A. Massey and R. C. M. Pearson on sick absence among munition workers (Dec. 12, p. 694), in which the authors state the value of industrial medicine, I am at a loss to understand certain aspects of both the figures given and the mode of their presentation.

First, although they state in their conclusion that "consideration of factory working hours is inseparable from the problem of sick absence," no indication is given of the hours worked by the seven firms described nor even of whether these are comparable or widely different for males and females. Again, although it is stated that "in explaining the higher absentee figure for males . . . the greater physical demands made of males by the nature of their work is also a relevant factor," very little indication is given as to the nature of the work performed, beyond saying that it is engineering, which, to say the least, is divided into "light" and "heavy" engineering. I appreciate that security considerations demand the withholding of many relevant particulars, but, even so, a division into the above category would have been very helpful and would not have imparted confidential information.

Secondly, although the authors state that their figures show a higher sick absence rate for males, it will be seen that this condition in fact prevails in only two of the seven firms they have examined—namely, Firms 3 and 7, both of which, in my opinion, should not have been included, because the former had an insufficient number of females to afford a basis of comparison, and the latter shows figures so different from the other five firms as to indicate special circumstances demanding further investigation.

In the remaining five firms the rates for males and females are to all intents and purposes approximately equal. In comparing this with my own figures for the same period relating to a number of females somewhat in excess of the total of the seven firms examined by Drs. Massey and Pearson and to a somewhat smaller number of males, all engaged on light engineering and working regular overtime, I find an entirely different state of affairs, as shown by the table below:

Percentage of Workers Absent, Sick, etc. (All Causes), Month by Month

Source	Sex	Nov.	Dec.	Jan.	Feb.	Mar.	April
Drs. Massey and Pearson (Table III)	Males	8·2	7·1	9·1	8·5	8·5	8·7
	Females	7·5	6·4	8·0	6·8	7·5	8·6
Figures obtained by myself	Males	1·95	1·8	1·7	3·0	2·2	3·2
	Females	3·8	3·8	4·2	4·6	3·9	2·6

In my case the over-all rate of sickness absence is only about half of that shown by Drs. Massey and Pearson, with the rate for females almost twice that of the males. It is difficult to understand this disparity, particularly in view of the authors' statement that the equivalent of only 50% of males and 45% of females lost time from sickness in the six months under review. My records show that at least 33% of all operators lost half a day or more by absence from all causes in a review of one month, and that 45% of all absence was caused by medically certified sickness of more than three days' duration. On this comparison the sickness rate should be less than my own, instead of being twice as great.

The authors do not, however, state explicitly whether their figures relate to medically certified sickness of three days' duration or over, or whether absences of half a day to three days are wholly or partially included. Their Table IV, however, implies that short terms of absence are excluded from all categories other than "other occupational diseases," which have an average duration of absence of, say, 10 hours as opposed to 65.8 hours for colds. I most heartily endorse the authors' recognition of the need for "improved and standardized sickness records relating to factories," and, failing this, suggest that for figures to be valuable, information as to exactly what they cover must be most precise and explicit.

Lastly, I do not agree with the authors' conclusion that "the health of the munition workers . . . is on the whole maintained." Apart from the fact that their figures in Table III show one in every twelve workers incapacitated by sickness at any given time, those same figures show, if not a persistent tendency to rise from November to April, at least an absence of the seasonable drop which one would have expected by April. I have sickness records dating back to January, 1939, and in that and every succeeding year until 1942 the sickness rate has almost doubled in January and February and returned to normal by April. In 1942, however, no return to normal has occurred; the figures, having fallen only slightly in April and having exceeded the January value for most of the year, are still steadily climbing. The absence of influenza epidemics in 1941 and 1942 should increase the probabilities in 1943, and with a resultant potentially increased sickness rate. It therefore appears that every possible measure in preventive medicine should be taken against the winter incidence of colds and influenza in the factories, and that serious consideration must be given now to the problem of working hours. While for a short spurt the health of the workers can stand up to long hours, for a sustained effort long hours can only be done at the expense of health.

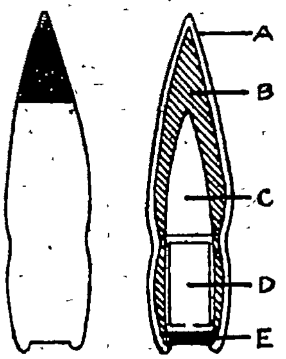
The medical profession must play its part in advising industrial managements of the long-term factors of their policy on the health of the employees, and in particular it must assist in adjusting working hours in relation to the work done and the conditions prevailing. These conditions include the demands made of workers by Civil Defence duties, the domestic situation in homes where both the man and wife are working, the decreased supplies of food available and the increased shopping difficulties in obtaining them, the increased difficulty in obtaining domestic help, laundry, labour-saving appliances, and even suitable housing accommodation itself, together with travelling and transport difficulties. Working hours should be so related to all of these factors that demands to increase output by working long hours do not defeat their own ends by causing excessive sickness absence.—I am, etc.,

JACK TARSH.

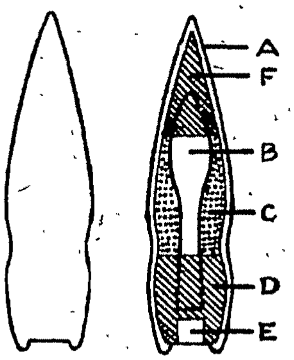
German Explosive Bullets

SIR,—In July, 1942, an enemy aircraft crashed and in doing so thousands of rounds of ammunition were scattered about. These were seized by sightseers, and no doubt many a mantelpiece is now decorated with them. As the result of a remark passed by a member of the public that this ammunition was explosive I investigated it, and found that some of these bullets contained an explosive charge and phosphorus. This information was passed on to the correct quarter.

Mr. A. J. Blaxland (Dec. 5, p. 664) described a case of phosphorus poisoning. I have since been in communication with him and mentioned the affair of July, and the results I found were the same as those of Lieut. Wheeler. As Mr. Blaxland in his article had described only one type of phosphorus bullet, we wondered whether you thought it would be of interest or benefit to the medical profession if the three common types of German bullets were brought to their notice, subject to the permission of the censor. We both thought it surprising that if the experts were aware of the types and the dangers associated with them, the medical profession as a whole were kept in the dark, especially as now there seem to be more cases of injury as a result of haphazard machine-gun fire from the air. I have therefore, with Mr. Blaxland's consent, drawn diagrams of two further types and added a description of each.



TYPE 1



TYPE 2

There appear to be three types of German machine-gun bullets in use at the present time. All types are of the .312 Mauser pattern.

Type 1.—The outside of this bullet is copper in colour, and has its nose painted black for 1 cm. from the tip. The outer case is copper-plated steel (A in diagram) with an inner coating of lead (B) more solid in the nose. Inside the lead coating there is a hardened steel bullet (C) on the end of a detonator (?) (D), which is separated from the end of the bullet by a thin lead membrane (E). The ends of the casing are curled into the base, and the lead is visible from below. The detonator (?) is encased in a cylinder of copper-plated steel.

Type 2.—This is unpainted, being copper-coloured. The outer case is made of copper-plated steel (A). It has a lead nose (F) into which is set a hardened steel cone (B) which tapers as it leads towards the end of the bullet. The end is also set in a lead weight (D), which is bored out to fit the end of the cone. The hole is plugged with a lead plug (E). The intervening space (C) is filled with 10 gr. of phosphorus. It would appear that on impact the lead weight (D) slides up the cone (C) and splits the casing, and at the same time squeezes the phosphorus out.

Type 3 (the explosive phosphorus).—This type is described and illustrated by Mr. Blaxland and contains the detonator and pin. It can be recognized by the black band that is painted around the outside, leaving 1 cm at the tip copper-coloured.

—I am, etc.,

J. R. F. POPPLEWELL.

Three Years of Military Psychiatry

SIR,—May I be permitted not only to congratulate Dr. J. R. Rees on his promotion to the rank of Brigadier but also on his most excellent article under the above heading (Jan. 2, p. 1). In this he states that it has been decided at a conference that pensions would not be given to cases presenting "neurotic" symptoms. This is to adopt the French system of the last war with this difference, that "exceptional cases" are to be recognized. I therefore wonder what will constitute an "exceptional case" and who will decide this.

I expect that others like myself have already seen quite a number of cases, including not only the "dull and backward" but also definitely mental defectives as well as "psychoneurotics," who have given endless trouble since enlistment, and been subject to repeated punishments before it has been realized that their "mental condition" was responsible for their inability to adapt themselves to Army conditions. Only a few days ago a lad of about 20 years of age, who had been enlisted last September, was referred to me on account of "nocturnal enuresis." He had passed the medical recruiting board as quite fit, but admitted to me frankly that he had suffered from this trouble all his life.

While the efforts being made by Brigadier Rees and his assistants to find suitable occupation for these "misfits" in the Army are beyond all praise, my contention is that if more serious attention were given to nervous and mental manifestations before enlistment and more cases presenting these symptoms were rejected instead of being suspected as being malingerers a great deal of time, trouble, and expense would be saved.—I am, etc.,

Exeter. RICHARD EAGER

Joint Committee on Rheumatism and Orthopaedics

SIR,—Drs. Ray, Heald, and Nissé are not correct (*Journal*, Jan. 9, p. 54). There are twelve members only of this committee, of whom six represent the British Orthopaedic Association. I am one of these, and although my name is mentioned twice in the published details I am a singular fellow (R.C.S.)! Your correspondents mention two of the physicians as being concerned with the work of the British Red Cross Clinic for Rheumatism, but they omit to note that two of the orthopaedic representatives are also on the staff of that organization.

The fact remains that the formation of this Joint Standing Advisory Committee is an important step forward in the furtherance of plans for collaboration which both the Empire Rheumatism Council and the British Orthopaedic Association keenly desire. Both have very large contributions to make in a service of great national importance for the prevention and treatment of crippling disability. Obviously the committee will have to consult other groups and individuals, working for the same cause.—I am, etc.,

Exeter NORMAN CAPENER.

Promanide in Local Treatment of Tuberculosis

SIR,—The importance of recent work in the U.S.A. and in this country on the effect of promanide (promin) on experimental tuberculosis in animals can hardly be exaggerated.

Efforts to apply, without too much delay, the results of this experimental chemotherapy to the treatment of the disease in man are to be welcomed. As one who has followed this work with the keenest interest since its inception in the laboratories of the Mayo Clinic, may I submit some observations prompted by the appearance in your *Journal* of the paper by Prof. W. H. Tytler and Dr. A. D. Lapp (Dec. 26, p. 748).

It is to be hoped that an adequate supply of promanide will be made available to those in a position to repeat and extend such tentative clinical trials as have already been made, though its use in an uncontrolled and unscientific manner is certainly to be deprecated. At present it is extremely difficult to get a supply of promanide.

The possible methods of application of the drug, as well as the types of lesion to be treated, deserve serious consideration. It would seem to me that cases in which it is proposed to make clinical trial by local application should be unconnected with a focus of deeper-lying disease, as such latter cases are unlikely to make a permanent response unless the underlying lesion (say, in bone, joint, or glands) is quiescent or can itself be directly attacked by the promanide. In Case 2 of Tytler and Lapp's series, in which the results are described as "spectacular," the two abscesses which healed with such extraordinary rapidity following the injection of promanide jelly appear to have been isolated metastatic soft-tissue lesions unconnected with a contiguous and deeper-lying focus of disease. If such selection is not observed the likelihood of failures is great, and may effect the premature disrepute of a possible new and highly important—even though extremely tentative—form of treatment.

It seems important, too, that cases treated with promanide should be controlled, so far as is possible, by very careful comparison with numbers of similar cases treated by accepted methods. I have two cases under my care comparable to Case 3 in Tytler and Lapp's series—one of tuberculosis of the dorsal spine, the other of tuberculosis of a hip-joint. Both had huge abscesses, one of which was about to point, despite repeated aspirations. Both of these abscesses absorbed in three months during a time when natural heliotherapy was possible, and neither shows any signs of recurring.

One mechanism of spread of the tuberculous process is through the lymphatic channels. Would it not, therefore, be worth while to attempt the introduction of promanide more directly into the lymph system? Dyes and Indian ink have been introduced, by way of the fauces, into the lymphatic channels and glands in the neck of rabbits and cats, the better to study the anatomy of those structures. Why not attempt a similar route for the introduction of promanide in cases of tuberculous cervical adenitis?

In connexion with some chemotherapeutic research in experimental tuberculosis to which I was witness in the Leningrad Institute of Tuberculosis, lesions were prevented from developing in the lungs of guinea-pigs and rabbits if, at the same time as the infective material was injected intravenously, cobalt oleate was injected intrapleurally. Presumably this was an effect obtained through lymphatic absorption of the cobalt oleate into the lymphatic channels of the lung. Would not a similar route be worth trying in the case of promanide, both in experimentally induced pulmonary tuberculosis in animals as well as in cases of the disease in man? M. R. Castex, E. L. Capdebourat, and E. A. Pedace (articles reviewed in the *Amer. Rev. Tuberc.*, March, 1942, p. 61) have shown that nebulized solutions of scarlet red and methylene blue when inhaled penetrate to the depths of the lung, provided the particles of the spray are small enough (not larger than $5\ \mu$). They treated 100 cases of non-tuberculous pulmonary suppuration by inhalations of nebulized solutions of prontosil, and come to the rather sweeping conclusion that "surgery is no longer needed in pulmonary suppuration." Such treatment is rendered difficult by the rapid absorption of the inhaled solutions, and this would, no doubt, hold true for nebulized solutions of promanide. Why not, however, look for a different vehicle for promanide in this connexion? Would not a solution, a suspension, or a solution-suspension of promanide in an innocuous substance of slow absorption (like, for example, poppy-seed oil—if promanide should prove soluble in such a medium) offer a means of attack on the lesions in the lung? It would, of course, be necessary for this purpose to find a solvent which would be of sufficiently low viscosity to permit of effective nebulization.

Perhaps cases undergoing external drainage of lung cavities by the Monaldi method would benefit by the introduction of promanide preparations directly into the cavity through the draining catheter. It may be, too, that the introduction of promanide into lung cavities without drainage would prove of benefit, particularly if this could be done with cavities of the closed type, when substances introduced would not be expelled by coughing. Certain types of lupus might also lend themselves to treatment by promanide, particularly the ulcerative type. And what is there to lose by trying preparations of the drug in cases of tuberculous meningitis, and introducing it for this purpose into the cerebrospinal fluid?—I am, etc.,

T. FRANCIS JARMAN.

⁂ As was pointed out in a footnote to the article by W. H. Tytler and A. D. Lapp, the drug under discussion is known as "promin" in the U.S.A. and in this country is now marketed under the name of "promanide."—ED., *B.M.J.*

Pasteurization of Milk

SIR,—Dr. A. H. Macdonald (Jan. 9, p. 52), writing on this subject, quotes a county medical officer as preferring raw to pasteurized milk. I, too, can cite one, perhaps the same, person who took a strong line against pasteurization *until* a child of his slowly succumbed to abdominal tuberculosis. His last word to me on the subject was: "My child was murdered by the farmers."

Can parents afford to wait for the much-desired time when all raw milk is rendered safe by the slow elimination of disease in cattle? Should they not rather demand instant security by a tightening up of the process of pasteurization so that once again it is adequately performed and reliable?—I am, etc.,

Northwood. ESTHER CARLING.

SIR,—Dr. A. H. Macdonald (Jan. 9, p. 52) states: "Sir Frederic Still on Dec. 28, 1938, wrote me: 'I think in several ways raw milk is to be preferred to pasteurized milk if only we could exclude infection in raw milk.'" Now, Sir, I enjoyed the friendship of Sir Frederic Still for forty years, and we did a good deal of work together with milk and wheys, and from what he repeatedly told me he dreaded the danger of tuberculous infection being conveyed to children through infected milk, and he advised pasteurization or boiling of all cows' milk before use. He was never tired of telling the story of a lady who consulted him before the last war and who was taking her child to a farm to convalesce after a digestive upset. He informed her that the danger from tubercle in cows' milk was so real that it was essential that all milk given to the child should be first pasteurized or brought to the boil. When she arrived at the farm she saw a cow with such a gentle face that she decided not to have the milk boiled. Three months later the child, previously free from tuberculosis, died from that disease, and a melancholy but now wiser mother was heartbroken at her neglect of the advice given. The cow referred to was killed and found to be riddled with tuberculosis —I am, etc.,

London, W 1. BERNARD MYERS.

SIR,—Lord Woolton, Minister of Food, has taken prompt measures to guard against the menace to public health of our milk supplies by consulting with milk interests as to a proposal requiring milk retailed in large cities to be heat-treated prior to delivery. Lord Woolton has thereby given his countrymen another example of his high practicality in statesmanship, and he is to be congratulated on a step which will prove of great service to public health, and remove one of the major causes that has been allowed to menace it far too long.

It is always to the good to have a lively and courageous opposition, even if it is to persuade us to swallow our milk with all its filth and latent possibilities! It is, at least, a caveat to the cocksure, and thereby has its uses. It has been a source of amazement to me that despite all the trouble and pains of zealous inspectors and watchful committees, milk production remains in such an unsatisfactory state, and so far removed from the goal of an abundant and really wholesome supply of this important commodity.

Farmers have complained to me that having taken infinite pains to secure healthy animals, clean and hygienic byres, and the milking technique carried out with the garb and zeal of a surgical operation, their product is carted off to the depots and mixed up with all "the rest." If this is really so, it is discouraging to the idealist to live up to any sustained standard of zeal, and makes one despair, despite all the flats and fuss, of ever securing more than a poor average. As matters stand to-day nobody could persuade me to drink a glass of milk that had not been adequately heat-treated—and so say most of us who know anything about it.—I am, etc.,

Bournemouth. J. ROSS MACMAHON.

SIR,—Some correspondents are not clear as to the meaning of "pasteurization." There are two processes: (1) the "holder" process—milk to be kept at 145 to 150° F. for 30 minutes and then immediately cooled to 50° F.; (2) the "high-temperature short-time" process—milk to be kept at 162° F. for 15 seconds and then immediately cooled to 50° F. Only milk treated by one of these processes can be called "pasteurized." The "flash" process for improving the keeping qualities of milk is undefined and is not "pasteurization." Tubercle bacilli are killed if kept at 60° C. (140° F.) for 30 minutes. It is worth noting that T.T. milk may not contain more than 200,000 bacteria per c.cm., whereas pasteurized milk may not contain more than 30,000 bacteria per c.cm. In connexion with milk the word "clean" is relative, and does not mean sterile. An infected milk can be "clean," and a dirty milk may be sterile after boiling.

Are there any figures for the percentage of cows infected with tuberculosis, and the number of epidemics spread by pasteurized milk? Have controlled and properly conducted experiments demonstrated the presence of tubercle bacilli in properly pasteurized milk?

Finally, one correspondent writes of water-borne typhoid epidemics as being accidental, but if a water supply shows faecal contamination such an epidemic is not accidental but inevitable.—I am, etc.,

Chalfont St. Peter H. G. WILLIAMS.

SIR,—The recent discussion on milk pasteurization is very opportune. We must all have had cases in which "glands" and vague gastro-enteric symptoms have developed in children a few months after taking school milk. Some parents having paid specially for T.T. or pasteurized milk used it in large quantities with excellent results, only to be confronted later with gland trouble after the children had started school milk; in consequence they became afraid of all milk and absolutely forbade it altogether. Not only is the milk itself in question, as is shown by its going sour overnight, but the whole of its distribution—dirty bottles left on the roadside for dogs to use as lamp-posts, dirty hands on full bottle necks, and dirty tools to uncap them, also dirty straws to suck it with. Both the public and ourselves would benefit by a full discussion of the whole milk question.—I am, etc.,

Peterborough A. M. PILCHER.

SIR,—It is fairly obvious that the opposition to pasteurization of milk is of the same nature as that which Jenner and Lister had to face, and argument is unlikely to convert the opponents. It must be admitted, however, that inefficient pasteurization is worse than none, and the necessary skilled supervision is hardly possible in small undertakings. After seeing a modern plant in operation I am satisfied that with proper methods the taste of the milk is unaltered and the vitamin content probably uninjured. In any case it would require a lot of vitamins to compensate for a few living tubercle or abortus bacilli. The time is, however, hardly ripe for compulsory measures.

Recognizing this, the Health Committee of this town formulated a scheme for establishing a pasteurizing plant under the control of the medical officer of health and with provision for bacteriological examination, etc. Producers were to deliver such proportion of their milk as they thought fit and to receive back an equivalent quantity pasteurized efficiently. They could then deliver either raw milk or pasteurized as the customers preferred; supplies of unsatisfactory quality would not be accepted for treatment. Inquiry was made as to whether the Ministry of Health would sanction a loan for the necessary capital expenditure, and the reply was that the council had no powers for such expenditure. Hence a promising scheme for the health of the community has had to be postponed until the pressure of public opinion compels the Government to act in the interests of public health.—I am, etc.,

Buxton. C. W. BUCKLEY.

Prophylactic Centres to Combat Venereal Disease

SIR,—May I through the medium of your *Journal* suggest the establishment of prophylactic centres throughout the country where those who have exposed themselves to the risk of having contracted V.D. could immediately attend for examination and treatment. Such a clinic was temporarily held during my tenure as R.M.O. at the London Lock Hospital, and fully justified, in my opinion, its establishment.

Subject to the decision of a body of eminent venereologists such a routine course might consist of: (1) urethral irrigation with approved bactericidal solutions whose adequate strength had been prescribed by a recognized central authority; (2) intramuscular injection of soluseptasine; (3) cleansing of the external genitalia with a solution of mercury biniodide 1 in 10,000; (4) these measures to be conducted under the supervision of a nurse or orderly trained in venereology, whose responsibility it would be to enter full particulars of all cases and to refer these subsequently to a medical officer for the routine tests.

The public have been so well informed of the dangers of promiscuity that I find they are now apprehensive and seek advice more readily than before. This especially applies to members of the Forces, who prefer to consult a civilian practitioner rather than their own M.O. This is my experience, which, I feel sure, is shared by my colleagues in private practice. The argument that such centres would serve to encourage promiscuity is, in my opinion, fallacious, as men and women are well aware of the gravity of the disease, and realize that the serious increase in its incidence justifies preventive measures being taken immediately, rather than to await the disease becoming established during a period which permits of other individuals having become infected.

By these methods I feel convinced that the rise in venereal disease would rapidly fall, and the large expenditure necessitated by the maintenance of venereal clinics would be considerably reduced. Here, surely, prophylaxis is better than cure.—I am, etc.,

London, W 1 E. SUTHERLAND-RAWLINGS

Treatment of Small-pox

SIR,—Referring to the communication of Col. S. G. S. Haughton (Dec. 19, p. 736) regarding the above, I beg to say that I dealt with an outbreak of this disease in 1902-3 and treated about 150 cases. The method of treatment adopted was the careful application to the vesicles and pustules of pure liquid carbolic acid by means of a very small camel-hair brush, and the results obtained were marked. It shortened the attack by causing the pocks to dry up. In all cases it modified, and in most cases prevented, the development of secondary fever, and obviated the usual fetid odour peculiar to this disease. It diminished the subsequent pitting and shortened the stay in hospital by 10 or 12 days. Several medical men tried this method of treatment and published their results, which confirmed these conclusions. One medical officer recorded that in his opinion it was the most efficacious treatment yet introduced —I am, etc.,

Edinburgh JAS. T. NEECH

Treatment of Chronic Ulcerative Colitis

SIR,—In diseases of unknown origin, and particularly in those like ulcerative colitis whose natural history runs a variable and unpredictable course with occasional spontaneous remissions, it is often possible to support a number of theories of causation with quite an array of evidence, though all the theories in question may prove later to be mistaken. Even a bacteriological cause in ulcerative colitis is not generally admitted, but I should like here to draw attention to the possible importance of anaerobic infection as a factor.

Perhaps the best-known organism to be incriminated is Bargen's coccus,[1 2] and it is stated to be oxygen-shy. More striking perhaps is the work of Dack, Heinz, and Dragstedt,[3] who investigated the organism in the colons of three patients who had undergone ileostomy and in whom "the organisms of the faecal current were therefore absent." In them the flora were "predominantly anaerobic," and two anaerobes were common to the three patients—a streptococcus, and another organism which was later described by the same authors as *Bacterium necrophorum*.[4]

On the treatment side Lynch and Felson[5] got the best effects by irrigation from oxidizing agents—potassium permanganate, hydrogen peroxide, and chloramin-T—and later Felson[6] claimed "encouraging results" from the introduction of oxygen gas into the colon. During recent years I have treated a dozen or more cases with enemas of a 5 or 10% freshly prepared suspension of zinc peroxide, usually given every second day. The foot of the bed is raised to encourage retention so long as possible, and a little belladonna added when the colon is irritable. Some cases have appeared to derive great benefit.

Against this background, I was interested in Dr. H. Neumann's article (Jan. 2, p. 9) reporting benefit from treatment by pneumoperitoneum, and I wonder whether this might be due to raising the oxygen tension of the tissue fluids in the bowel wall during absorption of the oxygen. I have tried oxygen breathing without result, but it is impossible to increase the oxygen in the tissues to any great extent by this method, and I should like to learn from physiologists as to the feasibility of treating patients in an atmosphere of oxygen in a pressure chamber.—I am, etc.,

Birmingham. J. W. RIDDOCH.

Preparation of the Hands for Operation

SIR,—Prof. G. Grey Turner's interesting account of preparation of the hands in the middle 'nineties (Jan. 9, p. 53) vividly recalls to me our varied methods of those pre-glove days. At Guy's, Howse, for whom I dressed, used to encourage us first to clean our fingers with full-strength liquor potassae and then to soak the hands for some minutes in carbolic lotion, 1 in 40. His results were uniformly good, and so were Galabin's, who pinned his faith on 1 in 1,000 perchloride of mercury, without the liquor potassae. Horrocks, another successful abdominal surgeon, used to open a bottle of Martell's 1 or 2 star brandy—7s. 6d. in those days—and he and his first assistant soaked their hands in it before proceeding to the mercuric lotion. After working under Horrocks I served as house-surgeon to W. J. Gow at the Royal Waterloo Hospital, who used carbolic 1 in 40 after a short soak in 1 in 20, and, in consequence, our hands were always as rough as files. We used to sterilize the marine sponges mentioned by Prof. Grey Turner—and I echo his regret—by soaking them throughout the previous night in 1 in 20 carbolic. However, while Gow's house-surgeon I heard him read a paper on a series of 50 consecutive ovariotomies, all completely satisfactory, in 1896. One well-loved and distinguished Guy's surgeon of this period had a most annoying run of bad luck, which he stopped by burning all his kid gloves.—I am, etc.,

Southsea. M. ASTON KEY.

SIR,—Forty years ago, before gloves came into general use at operating, much interest was taken in the questions of disinfection of the hands before operations and the general care of the hands. Most surgeons had some special technique, with or without scentific basis; many had fads. Measures intended to protect the hands from septic contact extended in some individuals to the ordinary personal sanitary procedures. A great wealth of literature, good and bad, especially in German, existed. The German *Surgical Year Book* (Hildebrand, *Jahresbericht über die Fortschritte auf dem Gebiete der Chirurgie*) devoted a special chapter each year to the subject.

Behind the cover provided by rubber gloves the present generation of surgeons has not been scientifically interested in the bacteriological state of its hands. Should the dearth of rubber become more acute it may well be that, of necessity, operations will be carried out with ungloved hands. Should that position arise, may I put forward the suggestion for consideration that scientifically it may be found desirable to use the gloves which may be available for the "dirty" cases, so to minimize septic contamination of the skin of the hands. Care of the hands and disinfection of the hands are complementary aspects of the one problem. They cannot be separated The problem is urgent and demands immediate and serious consideration. Scientifically we are back where we were at the beginning of the century.

As a basis for any such consideration may I direct attention to a small book, the best with which I am acquainted in English? It is probably out of print. It is *The Sterilization of the Hands: A Bacteriological Inquiry*, by the late Charles Leedham-Green of Birmingham (publishers: London, Simpkin, Marshall, Hamilton, Kent & Co., Ltd.; Birmingham, Cornish Brothers, Ltd., 1904)—a really excellent "objective" bit of work. Even if out of print, copies will probably be found in libraries. The book includes a remarkably full bibliography. I have no books available for reference so I cannot give further information, but there was a full-dress debate on the subject in the Section of Surgery at the B.M.A. Meeting at Oxford in 1904 and another at the Birmingham Meeting, Section of Surgery, in 1911. Detailed information will be found in the proceedings, which will be still available.—I am, etc.,

Marton in Cleveland, Yorks W. S. DICKIE.

Pancreatitis as a Complication of Mumps

SIR,—Pancreatitis is a very rare complication of mumps. Some paediatricians confess never to have seen a case. I remember one case in a girl of 10 many years ago. As cases of mumps do not congregate in fever hospitals as do other infectious diseases, and some cases, especially the mild ones, may remain undiagnosed, it is difficult to get an opinion about the frequency of this complication. It is said by some authors to be more frequent in some epidemics of mumps. In this connexion and in view of the prevalence of mumps at the present time it may of interest to report the following case.

On Dec. 14, 1942, I was called to a girl of 6 years suffering from mumps. She showed a slight swelling on the left side of the face, and developed a swelling on the right side later with very mild general malaise. On Dec. 22 I was called again to the child. The previous day she had started to complain of pains in her abdomen and sickness. She refused food, even fluids. The pains had grown worse during the night. In the morning she was constantly sick, and had been constipated for the last 24 hours. The little girl, whom I knew to be a very vivacious but not nervous child and talkative even when she had a high temperature, was lying in bed without taking any interest in her surroundings. She was pale, her face drawn, and she was moving about restlessly from one side to the other. The hands and nose were cold. She reminded me at first sight of certain cases of toxic diphtheria with severe affection of the myocardium. But throat and nose were normal, the liver was not palpable, and the heart did not appear enlarged. The temperature was 99.4° and the pulse 92. The tongue was coated, but moist She complained of pains in her abdomen, and indicated the regions above the umbilicus. On examination there was marked tenderness in the epigastric region, more so on the left side. The right hypogastric region was not tender. There was muscular resistance in the epigastric region. She was sick during the examination. To exclude an intestinal obstruction I ordered an enema, which had a normal result. The stool was of normal colour. In the evening the general condition had improved, but she still refused food except a little water with glucose. She had been sick again. The temperature was 99° F. and the pulse 90. The tenderness appeared to be less marked; urine had not been passed since the previous evening The next day her condition had improved considerably. She was taking light food and had not been sick again. There was still slight tenderness in the epigastric region. The urine was light in colour; albumin and acetone negative; no casts; the Benedict test showed green turbidity, but the precipitate did not turn yellow after 10 minutes. Recovery was uninterrupted.

The course of pancreatitis in conjunction with mumps is generally a mild one, and the symptoms often subside quickly Its nature and causation are still unknown. Pancreatitis is known to precede the swelling of the parotid glands.—I am, etc.,

London, W 9 F. MULLER.

Unwarranted Cardiac Invalidism in Children

SIR,—In a very interesting article on mitral systolic murmurs (Jan. 2, p. 8) Dr. William Evans says: "The need to recount the special features which characterize mitral murmurs receives emphasis in several departments of medicine to-day. Thus, in children the incidence of an innocent systolic murmur is high, and a faulty interpretation of this auscultatory sign is commonplace, condemning many of them unnecessarily to a life of semi-invalidism; routine medical examination of school children has inevitably subscribed to this episode. It should be a rule that no child is denied games and the healthy activities inseparable from a happy school life on account of a heart murmur of doubtful significance. Directly this suspicion has rested on a child arrangements for a special examination at a cardiac centre should operate automatically. Only in this way can unwarranted cardiac invalidism in children be avoided. Again, a young subject during convalescence from acute rheumatism is often confined to bed for several months because an innocent systolic murmur has been regarded as evidence of endocarditis or as a sign of mitral disease." Members of the Public Health Service engaged in school medical work will agree that Dr. Evans has called attention to a problem of first-class importance in the child life of the country. Whether they will feel disposed to agree with his suggested remedy is doubtful. My experience does not support his claim that unwarranted cardiac invalidism is avoided by attendance at a cardiac centre. On the contrary, such attendance is liable to confirm the invalid attitude of both child and mother.

Pari passu with the diminished incidence of juvenile rheumatism and heart disease in the last 40 or 50 years (thanks to social amelioration) there has been a remarkable growth in professional interest in the subject, culminating in the rise of "juvenile rheumatology" to the status of a special branch of paediatrics, and in the establishment by voluntary organizations and some public health authorities of "rheumatism supervisory schemes," including special clinics, schools, heart homes, and other arrangements for prolonged rest and convalescence

Meantime birth control has resulted in much fewer but much more precious children, with a corresponding increase in maternal anxiety for the welfare of the individual child and a craving for medical examination, advice, and guidance in his upbringing. In these circumstances the mention of "rheumatism" or "heart disease" is never without danger. Yet it is, in my experience, not uncommon to find these labels attached to children in whom I fail to find any history or signs or symptoms of these diseases. Sometimes the diagnosis has been made by the family doctor, sometimes by the school doctor, but quite often by a "specialist" at a rheumatism supervisory centre. When the label is attached by a specialist it has, quite naturally, greater significance in the minds of the parents and is correspondingly difficult to detach.—I am, etc.,

R. P. GARROW,
Medical Officer of Health.
Crouch End, N.8.

Adoption of Children

SIR,—My council is gravely concerned about the increasing number of adoptions which are being arranged, often without any proper safeguards, by private individuals, among them doctors, midwives, nurses, health visitors, and workers in Citizens' Advice Bureaux, none of whom has had the specialized training and experience essential for successfully carrying out so delicate a transaction. These persons, no doubt full of good will, think they are helping the mother (whether married or unmarried) of an unwanted infant and benefiting a childless couple, a wife whose husband is abroad on active service, or a lonely widow or spinster who wants an interest in life. We hear of infants being handed over like parcels at railway stations to persons about whom little or nothing is known by the no doubt kind-hearted intermediary, or of the arrival of such infants in completely unsuitable homes. To secure success in adoption long, patient, and skilled inquiries are essential; not only physical but psychological conditions need the most careful consideration. We wish to urge such intermediaries, with all the earnestness that we can command, to refer would-be adopters and parents of unwanted children to the established reputable and experienced adoption societies. These workers, through long experience, may hope to fit the right child into the right home, and thus avoid the creation of social wreckage and the causing of childish unhappiness which does not bear thinking about.

If and when the Adoption of Children (Regulation) Act comes into force many of the worst of these dangers to unwanted children will be safeguarded. Until that day we fervently beg all those interested to avail themselves of the services of trained workers and established organizations. Adoption may, and should, bring blessing and happiness to child and adoptive parents; it may, and too often does, produce results exactly the opposite. The unwanted child is the most helpless of human beings; let us bring to bear upon its problem all the skill at our command.—I am, etc.,

LETTICE FISHER,
Chairman, National Council for the Unmarried Mother and her Child.
117, Piccadilly, W.1.

Education Grants for Doctors' Sons

SIR,—I shall be grateful for space in your columns to make it generally known that under the will of Mrs. Emily Wilson Barkworth grants can be made to the sons of Fellows and Members of the Royal College of Surgeons who need financial assistance to meet the cost of their education at Winchester College. The number of candidates so far has not been sufficiently large to encourage the trustees to think that this limited application of the funds at their disposal will lead to a sufficient use being made of the income of the trust. They are, therefore, considering whether they should apply for permission to make selections from a wider field. The Council of the Royal College of Surgeons is anxious that Fellows and Members of the College should be aware of this generous bequest, and that, before consenting to any enlargement of the field, it can be certain that the applications from Fellows and Members are not likely to be sufficient to ensure full and satisfactory use of the trust. I shall, therefore, be grateful if Fellows and Members who are anxious to take advantage of this bequest will communicate with me at their earliest convenience.—I am, etc.,

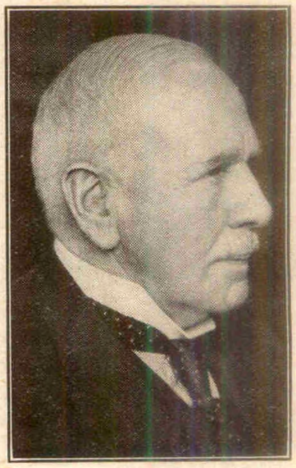
ALFRED WEBB-JOHNSON.
Royal College of Surgeons of England, Lincoln's
Inn Fields, London, W.C.2.

Obituary

SIR W. ARBUTHNOT LANE, BT., C.B., F.R.C.S.

Consulting Surgeon, Guy's Hospital

Bygone controversies will be recalled—but not revived—by the announcement of the death of Sir Arbuthnot Lane, which took place on January 16. An Irish ancestry and a Scottish upbringing combined to produce a combative and tenacious personality, partly concealed, but made more dangerous to opponents, by a mild and persuasive exterior. A man of undoubted gifts and insight, he seemed to take pleasure in the expression of extreme views, in season or—preferably—out of season, believing probably that by the clash of extremes a true balance can be maintained.



[Press Portrait Bureau

William Arbuthnot Lane was born in Scotland in 1856, the eldest son of Brigade Surgeon B. Lane, an Irish military surgeon. He was educated at Stanley House, Bridge of Allan, and received his medical training at Guy's, taking the M.B., B.S. of London, with the gold medal in anatomy and medicine, in 1881, and the F.R.C.S. in the following year, when he was only 26. The first of his innumerable publications dates from 1883, when he contributed to the *Transactions* of the Pathological Society of London a paper on fractures of the sternum, and to *Guy's Hospital Reports* on cases of empyema in young children treated by removal of a portion of the rib. His early work was almost entirely in bone surgery. He was interested in the human skeleton, its congenital deformities, the extent to which it is prone to accident, and its variations under pressure. He wrote extensively on such anomalies as cervical rib and sixth lumbar vertebra, also on knock-knee, flat-foot, and rickety changes in the spinal column and pelvis, and again on the changes produced by pressure—pressure changes in the skeleton revealing the labour-history of the individual, abnormal mechanical conditions of the hip-joint, the anatomy of the charwoman and of the cobbler, the effect of the corset on the abdominal viscera, and of the body on the mechanics of the foot. He once boasted that he could tell in the dissection room from the examination of the body of a manual worker what occupation he had followed during life. All these matters interested the young Lane. He saw the skeleton as representing the crystallization of lines of force. His belief was that the body bears certain mechanical relationships to its surroundings, and any change in those relationships has a corresponding effect on the anatomy, so that everything that Nature does to meet such an alteration in the mechanical relationships tends to shorten life.

As early as 1884 we find his name attached to nineteen papers in the medical journals, almost all of them dealing with fractures and deformities. These included an account of the abnormalities observed in the dissection room at Guy's, an annual review in which he collaborated during several years with Dr. (later Sir William) Hale-White. The earliest of many papers published in this *Journal* appeared in 1887 (**2**, 119). With the surgical department of Guy's his name was linked for half a century. He was also surgeon and later consulting surgeon to the Hospital for Sick Children, Great Ormond Street. His reputation rapidly grew, and some of the surgical procedures which his agile and emancipated mind thought out gained wide acceptance; his wonderful dexterity and surgical skill compelled the admiration of all. In the early 'nineties he was criticizing the splints then in use in fracture cases as likely to produce permanent injury and was anticipating to some extent the modern treatment of fractures. In 1893 he drew attention to the advantages of the steel screw in the treatment of fractures which failed to unite. His operation for cleft palate, introduced at the beginning of the present century, was widely followed.

It appears to have been about 1903 that Lane first published his views on the effect on general health of chronic obstruction of the large bowel, and from that time onwards his voice and pen never wearied in proclaiming that constipation was answerable for much of our disease and could be corrected by healthy habits of living. Practically all chronic diseases, he said, were merely symptoms or manifestations of intestinal stasis. So closely was his name attached to this doctrine that "Lane's disease: intestinal stasis" will be found in the medical dictionaries, as well as "Lane's operation: short-circuiting of the large intestine for chronic obstruction." His book *Operative Treatment of Chronic Constipation* appeared in 1904, and his printed papers and lectures on that theme from then onwards number at least fifty. Again and again he denounced the assumption in civilized communities that one action of the bowel a day was quite enough for health. Such assumption, he said, resulted in "constipation for twenty-four hours." If people would revert to the habit of "three motions daily," then many diseases, among them cancer, really due to intestinal stasis, would disappear. Such was the gospel he preached with the fervour of an evangelist.

The "kink of the ileum," which became known, perhaps with a little derisory significance in some quarters, as "Lane's kink," first appears in the title of a paper by him in 1910. By the "kink" he meant the anchoring of the iliac colon by the formation of thin bands or tags of peritoneum arising as a result of the excessive strain caused by the accumulation of faecal matter in the pelvic colon. This anchoring of the iliac colon, he exclaimed dramatically on one occasion, spelt the failure of civilization. He felt so strongly on this and other health questions that he did not hesitate to use the lay press—including the most widely circulated newspaper at that time—to bring them before the public. He was impatient at the lack of emphatic endorsement of them by the profession in general, and there were those who rebuked a man of such eminence for encouraging by his example doctors who courted the lay press for purposes of self-advertisement. There came a day when, as a protest, he resigned from the British Medical Association and founded the New Health Society. It was an unhappy controversy about which there is no need to say more. Sir Arbuthnot Lane's provocative statements always furnished "copy," as, for example, that "A glass of beer is better than a pint of tea," and "That which is universally accepted as true in medicine is almost always wrong." Even his platitudes were widely quoted; for example: "The future of the race is in the hands of our women." Not infrequently he castigated his own profession. In a speech at the R.S.M. in 1922 he declared that colectomy was necessary because of the hopeless ignorance and incompetence of the physicians. He would describe humorously how patients came to him and told him that a doctor had said to them, "For goodness' sake don't go to Lane. Whatever is wrong with you, even if it is only a sore throat, he will take out your colon." The controversies that he gathered round him made no difference to the affection in which he was held by Guy's men and many others, and in personal contacts nobody could be more charming.

Enough has been said already about Lane's frequent contributions to literature. Among the books which bear his name, in addition to *Operative Treatment of Chronic Constipation*, already mentioned, were *Cleft Palate and Adenoids* published in 1897, and *Operative Treatment of Fractures* in 1907. He was part-author of Carrington's *Manual of Dissections of the Human Body*, and author of the section on diseases of muscles and tendons in Treves's *System of Surgery*. A bibliography of his writings extending from 1883 to 1938 contains nearly 400 entries.

Lane was made a baronet in 1913. He was also Chevalier de la Légion d'Honneur. He married in 1884 Charlotte, daughter of John Briscoe. In 1935 he married, secondly, Jane, daughter of the late Mr. N. Mutch. His son, William Arbuthnot, succeeds to the title. Of his three daughters, the eldest took up a scholastic career, and achieved high distinction in the educational world. The other two daughters married members of Guy's staff, one becoming the wife of Mr. Harold Chapple, senior obstetric surgeon to Guy's, and the other the wife of Dr. Nathan Mutch, physician to the hospital.

Mr. H. L. EASON writes: Arbuthnot Lane will always be remembered at Guy's Hospital as the surgeon who first brought into practice the strict principles of aseptic surgery. These, combined with his uncanny dexterity and technique, made his unusual reputation while he was still a young man. His confidence in his own powers and in his own opinions made him an inspiring teacher and sometimes a combative critic of others. Unfortunately, others not endowed with his technique, and seeing the simplicity with which he appeared to do the most perilous things, tried to copy him, sometimes with unfortunate results. Of his work generally as a surgeon I am not competent to speak, but my memory reminds me, away from all records or dates, of two operations I saw him perform in 1897 or 1898. The first was his first treatment of a fracture by screws. It was a spiral fracture of the tibia, and Lane sent for one or two ordinary steel screws from the carpenter's shop and screwed the fracture right through the bone. Plating was, of course, a much later development. The second operation was for a large volvulus of the colon in a middle-aged woman. It measured about 25 inches in length and the colon was 11 or 12 inches in circumference. On the abdomen being opened the volvulus shot out and stood up like a bicycle tyre. Lane looked at it and said, "The only thing to do is to cut it all out." He therefore resected the whole volvulus, and the woman made a good recovery. The success of this operation probably suggested to his mind the possibility of his later, though possibly misguided, operations for resection of the colon. But, as has been said above, his unparalleled technique enabled him to do things with success which other men failed to do.

He was an Irishman, and he certainly had the faculty of trailing his coat-tails. In conversation he was difficult. Many people could find nothing to say to him, and he on his part had little to say to them except on the weather, and that in unstimulating phrases. His influence over his house officers and students was immense; but whether that influence was always to the good, in that they thought that what he did and preached they also could do and preach, the historian of surgery must decide. On the balance, however, he was a great surgeon, a brilliant pioneer, and a great teacher, the most distinguished Guy's surgeon of this generation.

G. W. CRILE, M.D.

We regret to announce the death on Jan. 6 at the age of 78 of Dr. G. W. Crile, Director of Research at the Cleveland (Ohio) Clinic, of which he was one of the founders.

George Washington Crile was born in 1864. He was educated at the Ohio Northern University and Wooster University (now Western Reserve University), and studied abroad in Vienna, London, and Paris. He received many honorary degrees, including the M.Ch. of the University of Dublin and the LL.D. of Glasgow. Dr. Crile was in turn lecturer and demonstrator in histology, professor of physiology, and professor in the principles and practice of surgery at Wooster University, and in 1921 played an active part in founding the Cleveland Clinic Foundation. He served as a brigade surgeon in the Spanish-American War in 1898 in Cuba and Porto Rico. In the 1914-18 war he saw service in France as Director of U.S.A. Base Hospital No. 4, Lakeside Unit; in 1919 he received the C.B. (Honorary Member, Military Division, 3rd Class), and in 1922 was made Chevalier, Légion d'Honneur. Dr. Crile was a member of many professional and scientific societies, and received several prizes and medals in recognition of his contributions to medicine. Among his publications were works on *Surgical Shock* (1897), *Haemorrhage and Transfusion* (1909), *Anoci-association* (with Lower, 1914), *Origin and Nature of the Emotions* (1915), and *The Surgical Treatment of Hypertension* (1938).

For the following appreciation we are indebted to Sir WALTER LANGDON-BROWN:

George Washington Crile's earliest work to command attention was concerned with anaesthetics, and he was one of the pioneers in blood transfusion. The conditions calling for this procedure naturally turned his mind to the study of shock. In the course of these researches he, like W. B. Cannon, turned W. H. Gaskell's great work on the sympathetic nervous system to admirable clinical use. In the retrospect it is curious to observe the lengthy time-lag between the physiological discoveries and their practical application. Cannon pointed out that the effects of sympathetic stimulation were all originally designed to activate the body for a struggle and to increase its power of defence. Crile went on to show how under less primitive conditions these effects, failing to find their appropriate motor outlet, produced perturbations which are so often mistaken by the sufferer for symptoms of organic disease. " Men's fear," he said, " is manifested in terms of his ancestral physical battle in the struggle for existence. He cannot fear intellectually, he cannot fear dispassionately ; he fears with all his organs. . . . Nature has the one means of response to fear . . . it is always physical. Under modern conditions of life neither fight nor flight is *de rigueur*. The individual under the influence of fear may be likened to an automobile with the clutch thrown out but whose engine is racing at full speed." And so in this vivid way he focused attention on the physical manifestations of psychological disturbances. Closely linked with this was his theory of " nociceptor," a view recently extended by Sir Thomas Lewis to include other receptors of painful stimuli. The nociceptor may be defined as the nerve-endings which through their sympathetic reverberations initiate a degree of shock often incommensurate with the severity of the lesion. Crile pointed out the instructive way in which animals engaged in mortal combat tried to seize on those areas of the antagonist most plentifully endowed with nociceptors. These are the views which attracted most attention to his work. He did not discover adrenaline as has been stated ; Schäfer and Oliver, as is well known, first prepared a potent extract from the adrenals, from which Takamine isolated adrenaline. Langley pointed out that it had the same effect as stimulating the sympathetic, and Crile seized on that idea, making use of adrenaline as a direct stimulant to the accelerator nerves of the heart—e.g., in collapse under anaesthetics. Some of Crile's later ideas found less general acceptance, but the work of his middle period has already passed into the general stock of medical ideas, even if their origin has been forgotten.

ROBERT BOYD, M.D.GLAS.

The death of Dr. Robert Boyd came as a great shock to his many friends in Manchester, and not least to members of his own profession, for whom he had done so much good and useful work.

Born in 1872 at Barr in Ayrshire, Dr. Boyd was educated at the Ayr Academy and at Glasgow University, where he took the M.B., C.M. in 1893, later proceeding to the M.D. After qualification he spent some years in house appointments, notably at Huddersfield. Later he served in the South African War, and in 1903 settled in Manchester. Here his absorption in his profession and his tremendous capacity for work soon ensured a large and busy practice, in which he was actively engaged to the time of his last illness. His chief hobbies, apart from his daily work, were the B.M.A. and local medical affairs, and the high esteem in which he was held by his professional brethren was well shown by the offices to which they elected him. He was chairman of the Manchester Division for 2 years and vice-chairman for 8 ; a member of the executive committee from its inception in 1915 ; a member of the Panel Committee from its start in 1913, and vice-chairman for 12 years ; and a member of the Branch Council for 20 years. Centrally he was a Representative for 20 years, being particularly concerned with the welfare of the family doctor, and proud to have taken an active part in starting the General Practice Committee, of which he became a member. For the last four years he was a member of the Insurance Acts Committee, having also served on the Hospitals Committee. Quiet, unassuming, never seeking the limelight, Boyd was a man of whom his profession may feel justly proud. By patients and colleagues alike he will be sorely missed.

We regret to announce the sudden death of Dr. **George Kenworthy Thompson** at Derby on Dec. 26. Born in 1887, Dr. Thompson was educated at Uppingham School and Manchester University, where he graduated M.B., Ch.B. in 1911 and in 1914 obtained the D.P.H. He held several hospital appointments after graduating and was assistant tuberculosis officer in Cheshire before joining the R.A.M.C. in 1915. He served in Gallipoli, Mesopotamia, and India, and on returning to civil life in 1919 became chief assistant medical officer of health in Derbyshire. He resigned this post in 1921, and from then until 1940 he was in general practice, first at Sedbergh, then successively in Cheshire, Essex, and at Coventry. Throughout this time, however, Dr. Thompson maintained a lively interest in public health activities, and he continued to hold various appointments with local authorities. When he left general practice in 1940 he became assistant medical officer of health in Derby. He was in Derby and then Mansfield for some time, and ultimately held the post of assistant medical officer of health for Northamptonshire. He had been a member of the B.M.A. for 30 years. Dr. Thompson was popular with staff and patients alike, and his untimely death will be regretted by a wide circle of friends. He is survived by a widow and three daughters, one of whom, Dr. B. Mary Thompson, is serving in the R.A.M.C.

In the *Journal* of Aug. 8, 1942 (p. 177), we published a brief obituary notice of Temp. Surg. Lieut. Eric Beresford Riding, R.N.V.R. We have now received the following appreciation from R. H. R.: Riding was a delightful companion, having a ready wit and a remarkable art of mimicry. Any function he attended was bound to go with a swing. He played soccer for the university for many years and was a natural athlete. Apart from public health, in which subject he passed with distinction, he did not strive after academic honours, but he was recognized as a sound student and a trustworthy, common-sense doctor. His maritime contacts and interests were many, and, if his end had to come in this war, it is perhaps fitting that it should have happened at sea.

The Services

Capt. G. O. Brooks, G.M., and Lieut. F. A. Macrae, R.A.M.C., have been awarded the M.C. in recognition of gallant and distinguished services in the Middle East.

Capt. K. Mariswamappa, I.M.S., has been awarded the M.C., and Brigadier (local) B. C. Ashton and Major (temp. Lieut.-Col.) V. E. M. Lee, I.M.S., have been mentioned in recognition of gallant and distinguished services in Iraq, Syria, and Persia during the period April, 1941, to Feb., 1942.

CASUALTIES IN THE MEDICAL SERVICES

Surg. Lieut. **James Langford Brownrigg MacFarlane**, R.N.V.R., was killed in action in H.M.S. *Achates* in December. He was born 28 years ago, the second son of Dr. and Mrs. J. E. MacFarlane of Whitley Cross, Reading, and received his professional education at St. Mary's Hospital, qualifying M.R.C.S., L.R.C.P. in 1941. Before entering the R.N.V.R. in May, 1942, he held the post of house-surgeon at Park Prewett Hospital, Basingstoke. He was a member of the B.M.A.

Temp. Surg. Lieut. **Archibald Barr Aiton**, R.N.V.R., is included as " missing, believed killed " in an Admiralty Casualty List published on Jan. 13. He was born on Sept. 3, 1917, and was educated at the University of Glasgow, where he graduated B.Sc. in 1938 and M.B., Ch.B. in 1941. He had held the post of house-physician at Stobhill General Hospital, Glasgow, before entering the R.N.V.R. in October last year. His home was at Strathaven, Lanarkshire.

Col. **Charles Frank Burton**, M.C., who was reported missing in the *Journal* of April 25, 1942 (p. 540), is now presumed to be dead. He was born on Jan. 16, 1889, and received his professional education at the London Hospital, qualifying M.R.C.S., L.R.C.P. in 1913. He served in the war of 1914-18, in the R.A.M.C., S.R., and was awarded the M.C. in Sept., 1918, the official citation reading as follows: " In his skilful leading of the stretcher-bearers on all occasions he has always shown great coolness under the heaviest fire." After the war he took a permanent commission as capt. in the R.A.M.C., was promoted major in 1926, lieut.-col. in 1938, and col. in 1941, and at the time of the Japanese invasion was holding an appointment at Singapore.

Capt. **Albert Joseph Antaki**, R.A.M.C., who is included as " died " in an Army Council Casualty List published on Jan. 15, entered the Palestine Section of the R.A.M.C. as lieut. in July, 1941, and was promoted capt. a year later.

Prisoners of War.—Major F. W. Allinson, I.M.S., Capt. R. W. W. Brown, R.A.M.C., Capt. W. A. W. Chapman, R.A.M.C., Capt. A. W. Chester, R.A.M.C., Temp. Lieut.-Col. G. F. A. Condon, I.M.S., Capt. A. H. R. Coombes, R.A.M.C., Capt. J. A. Falk, R.A.M.C., Capt. A. W. Frankland, R.A.M.C., Capt. J. A. Glover, R.A.M.C., Lieut.-Col. J. Huston, R.A.M.C., Acting Lieut.-Col. W. G. Kennedy, I.M.S., Capt. P. M. Kirkwood, I.M.S., Lieut.-Col. J. W. Malcolm, O.B.E., M.C., R.A.M.C., Capt. G. K. Marshall, R.A.M.C., Capt. H. V. Morris, I.M.S., Major T. F. O'Donnell, I.M.S., Capt. C. S. Pitt, R.A.M.C., Major J. White, I.M.S.

No. 52

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Jan. 2.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available

Disease	1943					1942 (Corresponding Week)

Stillbirths	234	25	30			148	15	46		
Rate per 1,000 total births (including stillborn) ..			37					60		

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Includes paratyphoid A and B for Northern Ireland.

‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales*, as was to be expected after the big drop in the preceding week, there was a very large rise in the notifications of infectious diseases. Measles was up by 4,101, whooping-cough by 350, acute pneumonia by 265, diphtheria by 208, scarlet fever by 105. The increase in measles and whooping-cough exceeded the decrease reported last week, but the incidence of the other diseases did not reach the level of a fortnight ago.

The incidence of scarlet fever continued to diminish in most areas, although the only decline of note was 46 cases in Yorks West Riding. The principal exceptions to the general trend were rises in Staffordshire of 81 and in London of 43 cases.

The largest increases in the notifications of diphtheria were those of London 29, Cheshire 39, and Derbyshire 36. In the last-named this was due to an outbreak in Chesterfield R.D. involving 34 people.

A small rise in the incidence of whooping-cough was general throughout the country, the largest being those of Yorks East Riding 45, Warwickshire 41, Staffordshire 37, and Essex 35.

The increase in measles began in mid-September and since then has been rapid. The cases are now five times as numerous as they were then, and have reached the highest level during the past twenty months. The largest rises during the week were those of London 442, Lancashire 417, Leicestershire 335, Essex 256, Middlesex 245, Nottinghamshire 242, Staffordshire 232, Yorks West Riding 227, Warwickshire 220. Over one-third of the total cases in the country were recorded in the two counties of Lancashire and Yorks West Riding.

There was an outbreak of 20 cases of dysentery in Derbyshire, Derby C.B., during the week. The incidence in most of the other areas fell, with the result that the total was 8 fewer than in the preceding week.

In *Scotland* there was a general drop in the incidence of infectious diseases. The cases of measles and scarlet fever were 114 and 105 fewer than in the preceding week, but in Glasgow the figure for measles rose by 5. Only 27 cases of dysentery were notified, the smallest weekly total during the recent months.

In *Eire* notifications of diphtheria and of scarlet fever were 45 and 39 more than in the preceding week.

In *Northern Ireland* there was a small but general rise in the notifications of infectious diseases.

Infectious Diseases during the Year

The past year has been notable for the large number of cases of dysentery and the very low incidence of enteric (paratyphoid and typhoid) fever. The drive for immunization against diphtheria has given disappointing results, and the total notifications were only slightly below those of preceding years. A comparison of the incidence of infectious diseases in recent years, compiled from the weekly returns in England and Wales, is:

	1942	1941	1940	1939	1938
Scarlet fever	84,932	59,111	65,573	78,201	99,413
Whooping-cough .. .	65,563	171,406	53,403		
Diphtheria	42,318	51,091	46,683	47,910	65,720
Measles	285,300	406,507	407,908		
Acute pneumonia . ..	42,487	50,514	47,712	42,275	45,117
Cerebrospinal fever	6,089	11,119	12,791	1,506	1,293
Dysentery	7,177	6,597	2,843	1,963	4,210
Typhoid and paratyphoid fevers	887	4,703	2,824	1,524	1,347

The incidence of cerebrospinal fever has fallen considerably, but remains at over four times the peacetime level.

Returns for the Week Ending January 9

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,808, whooping-cough 1,302, diphtheria 841, measles 14,153, acute pneumonia 1,091, cerebrospinal fever 87, dysentery 119, paratyphoid fever 5, and typhoid 8.

C. R. Donovan and M. Bowman (*Canad. med. Ass. J.*, 1942, **46**, 525) record their observations on encephalitis in Manitoba from 1938 to 1941 inclusive, with special reference to an outbreak of 509 cases during 1941 and a concurrent epidemic of 966 cases of poliomyelitis. During the four years serological tests were reported positive in 83 cases for Western equine virus, one for St. Louis, and one for Japanese B. The 1941 cases were distributed widely throughout the province and occurred mainly in August. About 70% were in males; 81% were 20 years old and older; 78 died—a case fatality of 15.3%.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

The Vice-Chancellor gives notice that the Sir William Dunn Professorship of Biochemistry is to be vacated on Sept. 30, 1943, by the resignation of Sir Frederick Gowland Hopkins, and that the Regius Professorship of Physic is to be vacated within the present academical year by the resignation of Dr. John A. Ryle.

The written part of the examination for the degree of M.Chir. will be held on Feb. 16 and 17, and the remainder on Feb. 26 and 27. R. H. A. Swain has been approved for the degree of M.D. in absence.

At a Congregation held on Dec 5, 1942, the following medical degrees were conferred:

M.D.—L. J. Bacon, R. A. Jones.
M B , B.Chir.—T. P. Pattinson (by proxy).

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW

Dr. P. R. Peacock will deliver a lecture on " Gastric Cancer: An Experimental Approach to the Problem of Causation " under the auspices of the Miss Weild Fund in the hall of the Faculty, 242, St. Vincent Street, Glasgow, on Wednesday, Jan. 27, at 4 p.m.

Medical News

Dr. J. A. Ryle, Regius Professor of Physic, University of Cambridge, has been elected Professor of Social Medicine at Oxford, with effect from April 1.

Prof. J. C. Drummond, Scientific Adviser to the Ministry of Food, will give a discourse on " The History and Knowledge of Scurvy and its Treatment " at the Royal Institution, 21, Albemarle Street, W., on Friday, Feb. 5, at 5 p.m.

A meeting of the Medico-Legal Society will he held at 26, Portland Place, W., on Thursday, Jan. 28, at 4.30 p.m., when a paper will be read by Dr. H. E. Cox on " Recent Developments in Food Legislation."

A meeting of the Royal Sanitary Institute will be held at 90, Buckingham Palace Road, S.W., on Wednesday, Jan. 27, at 2.30 p m , when there will be a discussion on " Healthy Housing."

The annual congress of the Ophthalmological Society of the United Kingdom will be held at the Royal Society of Medicine, 1, Wimpole Street, London, W., on Friday and Saturday, April 30 and May 1. Discussions on " Thyrotoxicosis in its Relation to Ophthalmology," to be opened by Dr. Russell Brain and Mr. L. H. Savin, and " The Scientific and Clinical Aspects of Night Vision," to be opened by Prof. W. J. B. Riddell and Air Commodore P. C. Livingston, will take place on the first and second days respectively.

The working of the Appointments System for out-patients which Guy's Hospital instituted some months ago is being hampered by doctors failing to comply with the procedure laid down. If they wish to send patients for examination they should write or telephone beforehand for an appointment with the member of the visiting staff concerned. Letters should be addressed to the sister-in-charge of the out-patient department, Guy's Hospital, London Bridge, S.E.1, telephone Hop 3500, Extension 11.

Supplies of benzyl benzoate are available for the preparation of the aqueous emulsion for the treatment of scabies, and if doctors or hospitals have any difficulty in obtaining it they should communicate with the Director of Medical Supplies, Portland House, Tothill Street, London, S.W.1, stating the quantity required monthly and the name of present or intended supplier.

Among recent activities of the Central Council for Health Education we may note the issue of a series of practical and compactly worded leaflets on various aspects of the health of the worker, under such titles as " Rest and Relaxation," " Be Kind to Your Stomach," " Care of the Feet." Industrial medical officers can obtain these leaflets and other health propaganda material by applying to the offices of the Central Council, Tavistock House, Tavistock Square, London, W.C.1.

The Council of Epsom College will shortly proceed to award St. Anne's Scholarships to girls attending Church of England schools. Candidates must be fully 9 and under 16 years of age, and must be orphan daughters of medical men who have been in independent practice in England or Wales for not less than 5 years. The value of each scholarship is dependent upon the means of the applicant and the locality and fees of the school selected. Forms of application can be obtained from the Secretary's Office, Epsom College, Surrey.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be sent to the Secretary.

TELEPHONE No.—B.M.A. and *B M J.*: EUSTON 2111.

TELEGRAPHIC ADDRESSES.—EDITOR, *Aitiology Westcent, London.* SECRETARY, *Medisecra Westcent, London.*

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

QUERIES AND ANSWERS

Income Tax

Remittances from Abroad

A. C. N. has held an appointment under a foreign Government for 23 years. He returned to England on Oct. 23, 1941, on sick leave, and hopes to go back in the near future. He was exempt from British tax as a non-resident for 1941–2, but has been assessed for 1942–3, as a resident, on the basis of the amount of his remittances to this country in 1941–2. The 1941–2 remittances were heavy and will not recur. A. C. N suggests that it is unfair that he should be charged 10s. in the £ on this amount when it would have been taxed at 8s. 6d. in the £ if it had been assessed for 1941–2.

*** A. C. N. has at least this advantage, that he is not liable for the first 5½ months of his stay in this country. Supposing, for instance, that he returns to his appointment in June, 1943, he will have been here for, say, 17 months, but have been liable only for the 12 months ending April 5, 1943. The basis of assessment for that year is legally the amount of the remittances received in the year previous; provided that those remittances represented income and not capital. (If the total amount remitted in 1941–2 was greater than the foreign income of that year, that point should be put to the inspector of taxes) If the figures are such as to create peculiar hardship it might assist if the facts were put to the Secretary, Board of Inland Revenue, Imperial Hotel, Llandudno, and a request made for some equitable concession, but a departure from strict legality is not likely to be conceded.

Single Person's Liability

F. D. asks, " How much should I allow for income tax on £300 per annum, all found? I am a single woman."

*** The tax due for the year to April 5, 1943, assuming that the employment covered the whole year, is calculated as follows:

Amount of remuneration		£300
Deduct—Earned income relief	£30	
Personal allowance	£80	
		£110
		£190
Taxable at 6s 6d in the £—£165 .. .. .. tax	£53 12 6	
" " 10s. " " £— £25 .... "	£12 10 0	
	£66 2 6	

Employment—Bad Debts

W. J. is working under the B M.A. scheme, for a practitioner who has been called up, on the basis that he is remunerated by half the profits of the practice. The inspector declines to make him an allowance for the bad debts booked but probably uncollectable.

*** The inspector is wrong. It is clear that in calculating " profits " some allowance or deduction should be made for bad and doubtful debts—that is a general commercial and income-tax rule—and as W. J.'s remuneration is measured by the amount of " profits " they should be taken into account in calculating his " share."

Fees Paid to the Royal College of Physicians

T. T. asks whether fees paid on election as a Fellow of the College are allowable as expenses.

*** No. The fees in such circumstances are in the nature of capital outlay rather than current expenses.

LETTERS, NOTES, ETC.

An Unusual Triple Complication of Pregnancy

Dr. G. P. **MERSON** (Zanzibar) writes: An Arab 4-para aged 35 was admitted to Zanzibar Maternity Hospital with a rather unusual history. The ante-natal period was uneventful except that hydramnios was suspected. The history given was that she went into labour at 6 o'clock in the evening with a normal show and slight loss of liquor. Next morning the membranes ruptured, with the loss of four gallons of liquor amnii. Pains continued and there was a large ante-partum haemorrhage. The midwife then examined her per vaginam. She found the placenta nearly completely separated and lying in the vagina, and a shoulder presentation with the arm prolapsed at the side of the placenta. The condition of the patient on admission to hospital was poor (pulse 110, subnormal temperature). On abdominal examination the position of the foetus was transverse, the head lying in the left iliac fossa. The placenta was hanging out of the vulva suspended by the cord, which had already been tied at the vulva. The arm was prolapsed and a hand was visible at the vulva. Although the patient's condition was poor she was still having very strong contractions at short intervals and, on account of this, immediate intervention seemed necessary. Under general anaesthesia with ether, decapitation was performed. The recovery was interrupted by the development of a small ischio-rectal abscess, which required incision. This case was interesting from the association of serious complications: (1) hydramnios; (2) central placenta praevia, with expulsion and delivery of placenta; and (3) impacted transverse lie.

Surgical Emphysema Complicating Pulmonary Tuberculosis

Dr. **GERALD H. COORAY** (surgical registrar, General Hospital, Colombo) writes: The case reports of Dr. T. B. L. Bryan (December 21, 1940, p. 868) and Dr. G. Hurrell (July 5, 1941, p. 16) respectively prompt me to record a similar case with the kind permission of Dr. B. E. Fernando, visiting surgeon, General Hospital, Colombo, under whose care the patient was admitted. A female Sinhalese aged 20 years was admitted to the hospital on August 22, 1941, with fever, cough, and pain in the chest of eight days' duration. She was pale and poorly nourished. Her temperature was 102° F. and the pulse rate 120. There were physical signs of a cavity at the left apex. The following day her temperature was 100.4° F., but she had suddenly developed surgical emphysema of the tissues of the upper part of the left chest. A radiograph showed a left-sided spontaneous pneumothorax. Her cough became more severe and her temperature began to vary between 99° F. in the mornings and 101° F. in the evenings. The surgical emphysema gradually spread to the tissues of the neck and face. As she was dyspnoeic surgical treatment was contemplated, but was refused by the patient. The emphysema gradually disappeared from the face and neck and her temperature began to settle down. Unfortunately, on September 1 she insisted on leaving the hospital and was therefore discharged.

Buerger's Exercises in Comfort

Dr. **WILLIAM CAMPBELL** (Edinburgh) writes: A patient recently treated in the wards of the Royal Infirmary, Edinburgh, by the intermittent venous occlusion machine applied to the thigh was instructed in Buerger's exercises when he was discharged. Three weeks later he reported to the ward to outline "Buerger's exercises in comfort" and to extol their effectiveness. His device was this. He had taken a pair of carpet slippers and through the toe of each driven a three-inch nail. Each end of a long stout piece of cord he had tied to each nail, so that it could be suspended over a hook in the ceiling, the slippers hanging some 24 inches from the floor. Thus he could seat himself in an easy chair with an adjustable back set low, and, with his feet in the slippers counterbalancing each other, indulge in his modified Buerger's exercises for several hours. His practice was to keep one foot on the floor, the other being counterbalanced well above the body for a period of from 2 to 3 minutes, and then to lower the one foot, thus raising the other for a similar period. Thus he would continue for 3 hours in the morning and 3 hours in the evening, reading a book the while and enjoying the mild exercise entailed. He maintained that its effectiveness was equal to that of the intermittent venous occlusion machine, and the clinical evidence in this case certainly corroborated his statement.

Diphtheria with Perforation of Larynx

Dr. J. D. **ROLLESTON** writes: The case described by Dr. R. W. Stephenson (Jan. 9, p. 60) under this title is most probably not an example of perforation of the larynx in diphtheria, of which, so far as I know, no instance has been recorded. Unlike scarlet fever, diphtheria does not cause deep ulceration. Dr. Stephenson's case seems rather to be an example of the very rare condition of which I collected seven cases, including one of my own, under the title "Non-surgical Subcutaneous Emphysema in Laryngeal Diphtheria" (*Brit. J. Child. Dis.*, 1928, 25, 185). The most likely explanation of the emphysema is that put forward by Natalis Guillot to the effect that as the result of dyspnoea pulmonary emphysema occurs, that vesicles on the surface of the lung rupture, and that air passes into the hilum of the lung and so into the mediastinum and neck. A similar condition is found in measles, whooping-cough, and influenza.

Fulminating Purpura and Adrenal Haemorrhage

Dr. **JAMES SHAW** (Smethwick) writes: With regard to the correspondence about fulminating purpura, etc., perhaps such conditions are more common than is usually believed, but the cases do not find their way into the literature. Some few years ago I was called to see a child who was well and dead within a period of about eight hours. The child came out in large purpuric spots all over the body, and rapidly succumbed. I do not think there was any definite history of illness or of any associated illness of any member of the family. Dr. G. J. Jones of this borough and I did a post-mortem examination, and found what we thought to be definite evidence of adrenal haemorrhage. Curiously enough a child was admitted to hospital to-day in the early evening and died just after admission. There were haemorrhagic spots all over the body, some head retraction (but no Kernig's, etc.), T. 105° F., R. 70, definite pneumonia, convulsions, and death. The parents stated that she was playing about until 1 p.m.; she died at 7.30 p.m. She was observed to be fretful at 1 p.m. They admit that she had a cold yesterday and the day before, and after some questioning I elicited the fact that another child had had measles recently. The rash, however, did not appear morbilliform in type, and the haemorrhagic spots were punctate-like and discrete.

Books and Diversions

Hospital libraries started in a small way have proved their worth; they are now recognized departments, at all events in the larger institutions. Then there is what may be termed "diversional" therapy and the better-known occupational therapy. A correspondent, who is herself an organizer of diversional therapy at an E.M.S. hospital and supervisor of hospital libraries in a wide area, suggests that these three departments should be linked under an experienced welfare officer, whose staff would include a trained librarian and assistant librarians, a trained artist and her assistants, and a trained occupational therapist. The welfare officer would receive a list of patients from the doctors, and her staff would visit the wards in the case of those patients too ill to leave their beds and would receive others into the workshop. This correspondent has found the following work possible for bed-patients: making soft toys and dolls, string belts, gloves, and slippers, also embroidery, knitting, sewing, light fretwork, etc., and for patients in the workshop: carpentry, plastic modelling, cane work, weaving, painting, bookbinding, etc. A large part of the staff could, she considers, be voluntary.

Post-herpetic Pain and Paresis

Dr. **MORRIS CUTNER** (St. Mary's Hospital, W.2) writes: In the *Journal* of Jan. 12, 1935 (p. 91), while reporting the relief of post-herpetic pain to be obtained by the application of "red light" to that portion of the spinal cord whence arise the nerves corresponding to the distribution of the herpetic condition, I suggested that ultra-short-wave therapy, then being introduced into this country, "would appear to be an even better method of treatment." Owing to the kindness of the honorary staff of this hospital it has been possible to try out the suggestion. The results obtained were so impressive (details of cases are given in the *St. Mary's Hospital Gazette* of November, 1941) that ultra-short-wave has been adopted as the routine treatment. The relatively few failures we have had have been in cases in which the treatment had been delayed. In no case where treatment was started within a few days of the onset of the eruption has ultra-short-wave therapy failed to relieve at first and then cure the pain. While the virus responsible for herpes zoster normally attacks the posterior root ganglion, if it is sufficiently virulent it may also affect the corresponding lower motor neurone, producing paralysis (*Journal*, Feb. 15, 1941, p. 234; Dr. A. Barham Carter and John B. W. Dunlop). This latter effect suggests the possibility that, although the pathology of acute anterior poliomyelitis is different, the use of ultra-short-wave therapy may be useful in the acute stage of the disease. Once the paralyses have shown themselves, persistence of the pathological changes already present in the cord may perhaps be prevented by the application of ultra-short waves to those portions of the spinal cord involved. They produce a long-lasting heating effect, increase the defence mechanism of the infected area and also the permeability of the capillaries (which, in the case of anterior poliomyelitis, are engorged).

Corrigendum

Dr. **NOEL F. ROWSTRON** states that the penultimate sentence of his letter (Jan. 2, p. 21) should read "a proportion default," not "a large proportion default."

THE NATURE OF THE RHEUMATIC CHILD

BY

DOUGLAS HUBBLE, M.D.Lond.

Assistant Physician to the Derbyshire Royal Infirmary; Physician to the Derbyshire Hospital for Sick Children

The rheumatic state in childhood has remained a profound and complex problem despite the observation and research of the last 60 years. There is little in the clinical story of the disorder as related in the textbooks of to-day which would break new ground for Cheadle, Goodhart, and Still. The problems which they stated—the nature of chorea and its relation to rheumatism, the aetiology of the rheumatic state and its relation to diathesis—still refuse solution. These clinicians would certainly remark that in the last 30 years interest and emphasis have shifted from the nature and reactions of the host to the characters of the invader, or, in Osler's parallel, from the soil to the seed. These bacteriological researches have produced much knowledge but no finality. A recent summary of them states:

> "According to one view rheumatic fever is caused by an unknown virus, an infection which is readily activated by haemolytic streptococci, but which may at times be activated under other circumstances. According to the second view the streptococci are themselves the cause of the rheumatic fever, the rheumatic symptoms being regarded as a peculiar type of host response conditioned by sensitization. It is not yet possible to decide between these views. It is a question whether the antibody response to the streptococcus infection which causes the rheumatic flare-up shows a significant difference from that encountered in individuals who show no such flare-up." (Holt and McIntosh, 1940.)

The comparative failure of these researches demonstrates the need for returning to the preoccupations of 50 years ago, to the study of the soil rather than of the seed, for it is here that the key to this "peculiar type of host response" must eventually be found.

The Mind–Body Relationship

There are other reasons for returning to the study of the disposition of the rheumatic child. There is no disorder in which the emotional and the physical components seem more inextricably mingled. There is no disorder in which the attempt to separate the psyche from the soma, the functional from the organic, is more baffling. It is a long step from the undischarged emotion of the choreic child to the adult dying from congestive heart failure, and of many of the steps in this unhappy pilgrimage we are ignorant. We shall not, however, advance our knowledge by refusing to recognize that this emotional tension exists in the child or by denying the possibility that such nervous instability can both initiate and condition physical processes. Psychiatry cannot discover the link between the emotional tension and the physical disorder; it can do no more than explore fully the emotional background. The other approach to this mind–body relationship is by way of neurophysiology, and it does not seem likely to be more fruitful than the psychiatric approach. Sherrington (1940) has discussed this problem in his Gifford Lectures, "Man on his Nature," and he writes:

> "There is, for instance, the condition 'anxiety.' None is, I suppose, more far-reaching as a warper of the mind. But where does neurophysiology contribute anything to the knowledge of the norm from which anxiety causes departure, and what has cerebral physiology to offer on the whole subject of 'anxiety'? The psychiatrist has perforce to go on his way seeking things more germane to what he needs. . . . The mental is not examinable as a form of energy. That in brief is the gap which parts psychiatry and physiology."

The introduction of the electro-encephalogram gave hope to some that the elucidation of this profound problem was imminent, and of this record it has been written (Gordon, 1939):

> "It is interesting to note that these changes in Berger's rhythm may be brought about not only by traumatic stimuli or by stimuli such as the shining of a bright light into the eye affecting the occipital cortex, but also by purely intellectual processes such as the effort to solve a mathematical problem."

It is obvious that not much can be hoped in this direction from a machine which makes little distinction between a crack on the head and the intellectual processes of an Einstein. It gives us *quantity* when we ask for *quality*, or, as Sherrington has brilliantly expressed it:

> "It has brought us to the brain as a telephone exchange. All the exchange consists of is switches. What we really wanted of the brain was, it would seem, the subscribers using the exchange—the subscribers with their thoughts, their desires, their anticipations, their motives, their anxieties, their rejoicings."

To write and talk, then, of "psychosomatic disorders" as is so often done to-day is to assume a bridge whose existence we but dimly discern and of whose nature we are ignorant. Such illnesses are better named disorders of personality, of the soil, or of diathesis. Yet we must not refuse validity, for these same reasons, to the psychological assessment of the personality of sick people before, during, and after their development of the physical signs of disease; for such studies, rightly interpreted, insist on a fundamental unity of mind and body—an integrity which can only be denied by materialists or mystics who have lost their way. Too often, however, in adults such studies have no therapeutic value. The process is irreversible. The arthritic joints, the ulcerated duodenum or colon, dominate the patient's psyche and the physician's efforts; but in children the lesion is, for the most part, subordinate to the growth of personality. The tail does not as yet wag the dog. The conditioning process of continuous adjustment to the environment goes on inexorably; but where the conditioning is too difficult or too rapid and where the adjustment is faulty, the parents, the physician, and the teacher can intervene to anticipate disaster and prevent it. The rheumatic state in childhood is to some extent a preventable disaster (since it occurs unusually in the well-to-do classes), and therefore the first questions to ask when we are confronted by a child with subacute rheumatism, with chorea, and with acute arthritis are: "Why did this child become rheumatic, and how can the aetiological factors be controlled?" To answer these questions is the further purpose of this paper.

What is a "Functional" Disorder?

It is necessary first to consider one other problem in nomenclature—the definition of a "functional" disorder. However this word is defined, it is still interpreted as denoting something of which the sufferer should be ashamed and something for which the physician may justly feel impatience or contempt. So that if I define chorea as a functional disorder, as I do, the immediate reaction of many people is: "Nonsense! How can the poor child help itself?" It is necessary at present to include under the description of "functional", disorders that must ultimately prove to be of widely different aetiology: the psychoneuroses; cerebral disorders, such as epilepsy, migraine, and chorea; the allergic disorders; the disorders of plain muscle—bronchial, oesophageal, gastric, colonic, rectal, ureteric, arterial; the disorders of cardiac rhythm, such as paroxysmal tachycardia; and many others as yet unclassifiable.

All this is so unsatisfactory that attempts are constantly made to provide a more exact nomenclature. Of recent years it has become usual to talk of physiogenic and psychogenic components of such disorders. This has been of little value because we are often unable to distinguish, as in the effects of cerebral trauma, what is physiogenic from what is psychogenic. Moreover, everyone agrees that physical disease may produce psychological disorder, and most of us accept as a fact that psychological states both indirectly and directly induce physical disease. A man is depressed, anxious, and fatigued, and develops a carbuncle, influenza, pneumonia, or herpes zoster; most of us are prepared to relate his psychological state to his ensuing physical disorder, just as we are prepared to believe that certain kinds of emotional stress may form the background for physical diseases, such as duodenal ulcer, ulcerative colitis, exophthalmic goitre, and rheumatoid arthritis. Changes in nomenclature cannot usefully run ahead of ascertained fact; for thus judgment is clouded and counsel confused. We must rest content with the adjectives "functional" and "organic" until the facts allow us to make further distinctions between them. If, then, I define chorea as a "functional" disease I mean that, although it has organic associations, it has a psychogenic component and no known structural pathology.

*The Clinical Significance of "Growing Pains"

"Growing pains" is the traditional name given to the pains in the limbs which occur commonly in children during school age. If the name was apposite it must have been generally inferred that such pains were both common and insignificant, that many children suffered from them and were afterwards none the worse. Such an estimate of their importance was strongly deplored by all physicians in early decades of this century. G. F. Still (1912) wrote:

> "The practical importance of recognizing the significance of these slight pains in the limbs in children—'growing pains' as they are too often called—can hardly be overrated. They may be the earliest indication of a rheumatic taint, and as such should always serve as a danger signal. To disregard them is to favour the onset of more severe symptoms, and it seems likely that active treatment in this early stage may not only cause the disappearance of pains but may also prevent those affections of the heart that are so distressing a feature in the rheumatism of childhood; certainly these vague pains call for the utmost care in prophylaxis, and a child who has once shown such symptoms requires continual care as to clothing, climate, and the prevention of exposure to cold and damp."

Robert Hutchison (1940) spoke more epigrammatically of "growing pains" in words which have echoed in the ears of several generations of medical students: "That, gentlemen, is a phrase which has crippled a great many hearts."

This was the general view, taught, accepted, and practised until after the last war, when the L.C.C. started its clinics for rheumatic children at the children's hospitals in London. Great numbers of children with pains in the limbs were referred to these clinics as suffering from incipient or actual rheumatic disease. It was soon obvious to the physicians in charge that they were not suffering from the rheumatic state; nor did they, in any significant number, develop it while under observation (Winnicott, 1931; Sheldon, 1936; Hawksley, 1939). Attention, both here and in America, during the last 10 years has therefore turned to the nature of these pains, their frequency, and their differentiation from the rheumatic state. They are variously regarded by different authorities as being due to "normal physiologic growth" (Shapiro, 1939), a view widely held in the nineteenth century; to fatigue and damp (Sheldon, 1936); to fibrositis (Seham and Hilbert, 1933); to postural deformities (several authors); and to emotional disorders (Winnicott, 1931, 1938). No one has yet attributed them to a deficiency of the vitamin B complex. Two of these views may be considered before discussing the nature of these pains. That the pains may be due to normal physiological growth is an opinion which will commend itself to few. The only physiological process to be accompanied by pain is childbirth, and to regard pain as a proper concomitant of growth is to live in a crazy world where the normal and abnormal coincide.

Nor is it to be accepted that fatigue is the prime cause of these pains. It is true that tiredness is frequently complained of by these children, but this fatigue is itself a symptom of ill-health. There is no fatigue in a healthy child that is not recoverable from by a night's rest. Tired children are ill children, and their illness may be emotional or physical in origin.

The incidence of these growing pains in normal children is extraordinarily high. Some observers have suggested that it is as high as 20% and even 40%; but a careful and extensive inquiry made by Kaiser (1927) in New York showed that out of 48,000 normal school children 7.1% complained of pains in the limbs. The incidence of cardiac rheumatism among 301,392 L.C.C. children examined in 1936 was 0.8%; so we may conclude that the incidence of growing pains among children is nine times greater than the incidence of rheumatic heart disease.

If the problem of the relation of growing pains to rheumatism is considered from another angle an immediate difficulty is disclosed, for there is no doubt that children who have developed rheumatic heart disease often give a history of pains in the limbs. Kaiser (1934) in his account of an investigation of 1,200 children with rheumatism said that 18% complained of muscle pains; and Sheldon reported that nearly 20% of 266 children with rheumatic heart disease gave a history of aches and pains in the extremities.

This, then, is the justification that the older physicians would have advanced for their warning as to the profound danger of growing pains. Their remedy was to treat all children with growing pains as potential rheumatics if their hearts were normal and as actual rheumatics if their hearts were under suspicion. This meant, as the quotation above from Still demonstrates, a life of partial invalidism, and it is not surprising, therefore, that the incidence of cardiac neurosis in the adult population is greater than the incidence of rheumatic heart disease. Paul Wood (1941) has written graphically of the childhood of these cardiac neurotics:

> "On the approach of the evil day when they will have to attend school they are filled with apprehension; if the dire event is not delayed by some happy illness (rheumatic fever followed by an open-air school is especially welcomed) they spend the next few years as trembling spectators of the rough-and-tumble of the miniature world about them. They evade as much as possible with the help of friendly coughs and colds; kindly doctors and soft mothers are at hand to protect them from the hazards of football, swimming, and the gymnasium."

As there is nothing in the disorders of school children that has more importance than this attitude of doctors and parents, let me recount the story of a pilgrim who narrowly escaped from this slough of despond:

Case 1.—This patient was 17 years old when I first saw him. His condition had been diagnosed as subacute rheumatism at the age of 12 by a well-known paediatrician on account of tachycardia and pains in the limbs. After this he became completely invalid. He was not allowed to go to school, but had a tutor at home. He was forbidden all games and swimming. He was kept in bed for a fortnight whenever he caught a cold, which he frequently did. His parents surrounded him with every circumstance of anxiety—they were convinced that his heart was "weak." Fortunately, it was not so difficult to convince the boy that his heart was normal. He started at 17 to swim and play tennis, and without his parents' knowledge he joined the Territorials just before the war. The start of the war found him in the ranks, and the violent change in his conditions of life was almost too much for him. He fainted several times on parade. Fortunately, the boy had spirit and the makings of a good physique, but his parents during the next year tried every manœuvre to get him out of the Army.

---

* The part of this paper concerned with growing pains was read to the Derby Medical Society on August 11, 1942.

His father's heart bled for him metaphorically, but his duodenal ulcer bled literally. Fortunately again, my opinion of his heart was firmly supported by Dr. Hugh Barber and Dr. Geoffrey Bourne. The boy remained in the Army, and some time ago successfully completed his Commando training.

The moral of this story is not that the original diagnosis was incorrect. It may possibly have been right. The moral is that such treatment is hopelessly bad even for a child with rheumatic heart disease.

Pitfalls in Diagnosis

Can this diagnosis between the child with active rheumatism and the child with growing pains be made with reasonable certainty? No doubt it can, but the following characteristic examples will illustrate the pitfalls in diagnosis and the errors in treatment.

Case 2.—A boy aged 10 complained of pains in his legs. His parents had kept him in bed as he was running a temperature between 99° and 101°. There was no evidence of infection, his heart was healthy, and his joints showed no inflammation. He had a mild secondary anaemia. He said that his pains were in his calf and thigh muscles. He slept badly, was difficult to control, cried frequently, and attacked his young sister without good reason. We kept him in bed some weeks without improvement, and then at his parents' instance took him to see a well-known paediatrician. He spent ten minutes looking at the boy, declared him healthy and slapped him on the back, told the parents to send him away to boarding school, and ignored me completely. The boy returned to health and remained well.

I learnt from this salutary experience that emotional disorder in children can be established as a positive diagnosis and not a diagnosis made simply by exclusion of physical signs. The only diagnostic sign in this boy was his emotional instability. The second lesson was that emotional disorder can cause signs and symptoms that are often thought only to be physically determined—pyrexia, tachycardia, secondary anaemia, and pains.

Case 3.—A boy aged 13 was referred from school clinic on account of a pain in his left elbow which had been present for a year. He was a healthy and alert boy of good physique with a sensible and cheerful mother. His pain frequently came on at school, and it was so severe that he often wept and had to be sent home. Equally, it might come on at home, as "last night when he was writing a letter to his father." He was very much attached to his father, who joined the Army 14 months ago. Pain frequently waked him at night and he slept badly. Six months ago he was seen by an orthopaedic surgeon, who found no disease but referred him for physiotherapy. There was no improvement after four months' treatment. No sign of ill-health was elicited on examination, and he was treated by *reassurance* that his pain betokened no disease; *explanation* that the pain was due to depression at his father's absence; *insistence* that he should carry on with what he was doing at home or at school, however great the pain; *sedative* (phenobarbitone gr. 1/2 night and morning) to ensure sleep and a quiet nervous system. These simple measures brought about relief from pain in a fortnight, and the boy has remained well.

This boy illustrated one point that is commonly overlooked: the necessity for removing the presenting symptom—i.e., pain—in these children. Quite often it seems that the emotional disorder which originally produced the symptom has disappeared and the child's entire preoccupation is with the pain. Remove the pain or give the child sleep and all is well.

Case 4.—A girl aged 8 was referred from the school medical department with pains in the legs and ? early chorea. The child was evacuated from Birmingham and now billeted with a foster-mother, who brought her to hospital. Her movements were continuous as the woman told the story of her fidgetiness, irritability, and sleeplessness. The movements were not characteristic of chorea. Her temperature was 99.5°, her pulse rate 120 a minute. The apex beat was in the nipple line, but there was a short systolic murmur at the apex. She had a kypholordotic stance, and her foster-mother, facing the child while I looked at her back, went on with her garrulous repetition of the patient's defects. The child's spine suddenly twitched into a well-marked scoliosis and then went back as suddenly to the midline again. She was admitted for a few days for observation away from her foster-mother. Her symptoms settled quickly; no further organic signs were discerned; her sedimentation rate and her sleeping pulse rate were normal. The billeting officer found another home for her, and she remained well after discharge.

These last two cases raise the question of orthopaedic treatment. It is wrong, as in Case 1, to expect the orthopaedic surgeon to diagnose emotional disorder. One must not hope to "gather figs from thistles," but the orthopaedist is not without sin in treating by physiotherapy a pain which showed no orthopaedic associations. The last child, who was beginning postural deformities, might have needed orthopaedic treatment provided the emotional difficulty was coincidently treated. The emotional origin of some postural deformities is increasingly recognized by orthopaedic surgeons. Bankart has written: "To find a scoliosis look at the child's back; to find its cause look at its mother's face." Hawksley (1939) found that "a frequent cause of growing pains is a postural or orthopaedic defect such as flat-foot, knock-knee, scoliosis, or bad stance; treatment of the cause in these cases nearly always gave relief."

I agree that it is fairly common to find a postural deformity in these children, but I do not agree that this is commonly a source of their growing pains. I have often caused the disappearance of growing pains in these children (as in Case 4) without treating their postural deformity. I agree again that physical exercise is good treatment for such children: the improvement of physical poise brings a coincident improvement in mental poise.

Growing Pains and the Subacute Rheumatic State

In Case 4, above, the subacute rheumatic state was very closely imitated. The pains, the temperature, the tachycardia, and the systolic murmur suggested a rheumatic carditis, and the fidgetiness and habit spasms mimicked true chorea. Such cases are not very uncommon, and it is admitted by all clinicians that an absolute diagnosis may be difficult. In this case a positive diagnosis of emotional disorder, the absence of evidence of an active carditis, and the therapeutic test of removal from environmental difficulties provided the correct solution. Yet it is such cases that the older physicians had in mind when they wrote of a "pre-rheumatic state," of "a latent rheumatic infection or toxaemia," of "subacute rheumatism," or of "latent chorea": a state which had for its presenting symptoms muscle or joint pains, fatigue, pallor, and an emotional instability.

This idea of latent infection or toxaemia makes little appeal to a generation which is inclined to discount the kindred theory of the septic focus. An infection which cannot be demonstrated either clinically or bacteriologically cannot be assumed to be present. Moreover, the notion that such cases show evidence of a pre-rheumatic state is open to two overwhelming objections—viz., (1) that all nervous children show these and similar symptoms; (2) that to treat such children as rheumatic is to make cardiac neurotics of them.

"But," the older physicians would reply, "a definite percentage of children with an active carditis associated with rheumatism give a history of what we have called subacute rheumatism." This is true, but in some of these children the symptoms are probably due to a coincident and active carditis. The number of children in whom the first and presenting symptom of the rheumatic state was growing pains alone *without* carditis was 9% in Findlay's series of 701 rheumatic children and 8% in Kaiser's series of 1,200. Shapiro (1939) suggests that it is possible by analysis of the type of pain felt by these children to make a diagnosis between subacute rheumatism and growing pains. It is obviously of the highest importance to attempt this diagnosis in the individual child, since growing pains do not lead to carditis and the pains of subacute rheumatism may do so. Shapiro concludes that growing pains come on at the end of the day or at night, wakening the child, that they are situated in the muscles of the thighs, and that the children show none of the other evidences of rheumatic activity; while the pains of subacute rheumatism are present in the morning and persist throughout the day, are made worse by walking and are situated in the joints themselves, and such children show other evidence of rheumatic activity. The most valuable sign in this differential diagnosis is the situation of the pain. If the pain is limited to joints, even in the absence of swelling, subacute rheumatism should be suspected. All agree that in a small number of cases immediate diagnosis is impossible, and Shapiro writes:

> "In a smaller group of patients who complain of painful extremities a clear-cut differentiation cannot be made. They have symptoms which suggest both the muscular pain of 'growing pains' and specific joint pain as well, together with some signs of infection. Such children need to be observed over a period of time before a definite diagnosis can be made."

More helpful in the positive diagnosis of growing pains is the presence of emotional disorder. The child is depressed or anxious, and shows this not alone by growing pains but also by behaviour disorders and disturbance of body function—sulkiness, irritability, fits of temper, sleeplessness (almost invariably present), fatigue, and lack of appetite. The therapeutic test of simple psychotherapy and sedation often confirms the diagnosis. There is now general agreement by physicians who have watched large numbers of these children with growing pains over many years that they do not, in any significant number, develop rheumatism. Sheldon (1936) examined 189 children with growing pains after a lapse of four years and found that only two had developed carditis. On the one hand, then, there is the fact that 9% of children with active carditis give a history of subacute pains which it may sometimes be difficult to distinguish from growing pains, and on the other the fact that of vast numbers of children under observation for growing pains only a negligible proportion develop active rheumatism. Can these two facts be reconciled?

I think it is wise to keep a more open mind on this question than is generally done to-day. It is generally agreed that children with growing pains who are under proper observation and treatment do not develop rheumatism. Is it certain that the same can be said of those children whose pains are neglected and in whom emotional disorder persists? I have notes of three children whom I had previously diagnosed as suffering from growing pains and who then disappeared from my sight. They reappeared in the out-patient department, after attacks of acute tonsillitis, at intervals varying from six months to two years, each of them with an active carditis. The fact that there is sometimes, as Shapiro and all other observers agree, this difficulty in deciding between the two conditions makes one wonder still whether this state of subacute rheumatism may not be an intermediate phase, in children predisposed to rheumatism, between growing pains and active rheumatism.

This matter of subacute rheumatism awaits clarification; it should be emphasized that it is an uncommon way for the child to enter into the rheumatic state. In so far as I have seen subacute rheumatism it has been easier to detect in those children evidence of nervous instability than to find unequivocal evidence of infection. In the effort to diagnose active rheumatism at the earliest opportunity there is no doubt that these cases have been given an importance out of proportion to their comparative infrequency. They have a great aetiological interest, however, for they raise the questions—Is there sometimes a half-way house to active rheumatism?; Could the process at this stage be controlled?

The Nature of Growing Pains

Four of the theories which have been advanced for the causation of growing pains—normal growth, fatigue, latent infection, and postural deformities—have been discarded already in the course of this paper. That growing pains may be due to fibrositis finds few supporters: Hawksley discovered only one or two cases among his 115. Tenderness at the site of the pain is remarkably absent in these children. Damp as a contributory factor can also be excluded in most cases. The remaining theory is Winnicott's suggestion that these pains represent an emotional disorder associated with the child's growth. "They are to be found," he writes, "wherever human beings are developing from babies into children, from children into adolescents, and from adolescents into adults." I have accepted Winnicott's theory as a basis for treatment in the many scores of such children I have seen in the last six years, and I am firmly convinced of its truth. These children's pains respond to the simplest psychotherapeutic and sedative measures, to the great improvement of their physical and nervous health. Statistics bring no conviction in this regard—it is a matter for personal approach and experience; but statistical evidence is provided by Neustatter (1937), who examined from the psychiatric standpoint a group of 40 children with growing pains, against several groups of controls. He reported that 34 out of 40 children with limb pains showed some degree of nervous disorder, as against 15 out of 40 picked children of good physique and 22 out of 40 in a group of rheumatic children. He concluded that these children with growing pains were "suffering from the effects of prolonged emotional strain."

It is common to find evidence in support of this theory of "prolonged emotional strain" in the papers of authors who attribute growing pains to other causes. Many observers have noted the fact that these children cry frequently, unlike the children with acute rheumatism. Hawksley says: "45% of the 115 patients with growing pains had at one time or another been reduced to crying with the pain. A feature noted by many parents was the tendency of growing pains to make their children sulky and irritable. Psychological maladjustment was unexpectedly frequent, resulting in unhappy school or home life."

It is concluded, then, that growing pains in children reflect a disorder of psychological adjustment and they are quickly removed by simple and appropriate treatment. Active rheumatism should never be diagnosed unless arthritis or carditis is present. The possibility that subacute rheumatism represents the growing pains of children predisposed to rheumatism cannot be denied. This consideration is only of theoretical importance in aetiology, and is of no account in the treatment of growing pains.

The Nature of Chorea

Chorea is generally defined as a manifestation of the rheumatic state whose morbid anatomy is an inflammation of some part of the cerebrum. It is open to anyone to draw a conclusion from the known facts, but the usual inference made from this definition is that chorea is a brain inflammation caused directly by the rheumatic invader. This definition and the inferences from it differ so remarkably from a legitimate conclusion based on the available evidence that a reconsideration of the facts is overdue. In the first place, chorea is a disorder whose structural pathology is quite unknown.

> "Microscopical changes," write Buzzard and Greenfield (1921), "in the central nervous system in cases of chorea have usually been conspicuous by their absence, but attention has been called to the occasional presence of hyperaemia and of small thrombotic lesions which, however, are by no means constant."
>
> Lewy—quoted by Findlay (1931): "Summing up the position in 1924, Lewy states quite categorically that changes are very seldom found, that these are of no definite nature and are no more than are to be observed in the brains of patients dying from any acute disease."
>
> Freeman (1933) makes no distinction between the morbid anatomy of the brain in acute rheumatism and chorea. He classes the changes in the brain with those seen in typhus and the rickettsias.
>
> Holt and McIntosh (1940) write: "There has been little constancy in the findings in patients who have died with chorea, and there is still some doubt as to the seat of the morbid process. Degenerative changes in the basal ganglia, the cortex, and the cerebellum have been described by Lewy and others in a number of instances. In other cases no such lesions have been found although carefully searched for, and one must assume that the disturbance is functional."

These authors define chorea as "a functional disorder of the nervous system characterized by sudden aimless, irregular movements often accompanied by muscular weakness and emotional instability." Kinnier Wilson (1928) writes: "Choreic motor disorder manifests itself through the pyramidal tracts, which must be in a condition of relative integrity for hyperkinetic symptoms to appear, and yet they exhibit some defect of function."

Chorea is a disorder which to-day steadily diminishes in frequency and severity. Even in days when it was more common and more violent Still records that "there are exceedingly rare cases in which it proves fatal by its violence. . . . Almost invariably if death occurs during chorea it is due to endocarditis or pericarditis." A survey of recently published necropsies suggests that the morbid anatomy described depends on the supervening rheumatic inflammation. The changes recorded in the brain are widespread from pons to cortex, and it can only be said of such changes that they are what would be expected of acute rheumatism by comparison with the morbid anatomy of other organs, and if these extensive lesions of meningo-encephalitis are proffered for the structural basis of uncomplicated chorea then they bear little relation to the clinical picture of the disorder.

That chorea is a functional nervous disorder unassociated with brain inflammation is borne out by clinical observation. It is accompanied by no pyrexia, by no leucocytosis, by no signs of inflammation in the cerebrospinal fluid, and by no raising of the sedimentation rate unless carditis is present. The movements of chorea cease completely during sleep, unlike the similar movements that are induced by encephalitis. Recovery from chorea is complete and there are never any organic nervous sequelae. The uncomplicated case of chorea runs its course, from onset to recovery, without one clinical or laboratory sign which indicates an infection or inflammation. I know of no other disease in which, without some positive evidence, inflammation and infection are generally assumed to be present.

It is possible that invasion of the brain by a virus, activated on the one hand by emotional stress and on the other by the haemolytic streptococcus, may give rise to the emotional and motor instability which is called chorea, without revealing its penetration by the usual signs of infection. This is an adequate and attractive theory, but without proof. It is accepted by most physicians that chorea is often preceded by a prolonged emotional strain, such as the "anxieties engendered in nervous children by the examination system" or by domestic stresses or, more rarely, by a sudden shock or fright. It occurred to Findlay that the "chorea induced by fright might be different in nature from that arising spontaneously; but of the 36 cases with a history of fright cardiac disease was present in 47%, and of the 254 cases in which no history of fright was obtained cardiac disease was also present in 47%, so that there seems little justification for such an assumption." It would be possible to quote from a dozen authors who deny that such emotional disorders have any aetiological significance in the development of chorea: believing as they do that chorea is caused by a rheumatic infection, these physicians cannot be expected to agree that it may also be initiated by the school inspector or by domestic infelicity. They therefore suggest that an attack by a dog, or whatever it may be, is too trivial an incident to occasion such a disorder. This will be generally accepted. The fright has the same relation to the ensuing chorea as the murder of the Archduke at Sarajevo had to the development of war in 1914. This view that chorea was often emotionally induced was firmly held by nineteenth-century physicians, and it is accepted as firmly by most physicians to-day.

Sheldon (1936) writes: "The important part played in the production of chorea by the stress of education cannot be doubted. There is often a history of some shock or fright at the beginning of an attack."

Carey Coombs (1924) states: "Nothing is more certain than that nervous stress precedes the onset of chorea in a number of cases—a number too large to be explained away."

Winnicott (1938) says: "In my own clinic I had no difficulty in collecting 50 cases of chorea following acute or prolonged emotional strain."

Gerstley *et al.* (1935), after a close clinical, psychiatric, and social study of 58 children in Chicago suffering from chorea, writes: "Psychic trauma seemed so intimately related to the actual onset in 22 cases as to force the question of its being the activating factor. Domestic discord was a prominent feature. It was plainly apparent in 32 families and extreme in 13. The onset of acute manifestations often followed a domestic crisis such as divorce, separation, desertion, drunkenness, and the advent of stepbrothers and stepsisters. Other types of emotional injury were common. In three girls the onset was related to attempted rape. In four others the child lived in continuous dread of assault by undesirable characters in the neighbourhood. One child was aware of the illicit sexual relations of her mother. In others the onset followed acute fright. In short, in our series psychic trauma resulting from fright or overwhelming grief stood out far more strikingly than did any history of infection."

A reflex of the Chicago underworld in the early 1930's! Of the 18 cases of chorea seen by me during the last five years four started acutely after a sudden fright. One child developed chorea actually during an air raid, in one it followed a few hours after a sexual assault, in one after an attack by a dog, and in the fourth after the child had been called to the front of the class by a school inspector and asked to recite. In six of the other children there was evidence of prolonged emotional stress either at home or at school. One child developed it after tonsillitis, and in three other children its onset accompanied an attack of acute rheumatism.

Two other facts in the aetiology of chorea concern social grouping and sex incidence. The social grouping in chorea is even more marked than in acute rheumatism. Most physicians can report instances of acute rheumatism among children of the well-to-do classes (see below), but chorea is rarely present among these children. Still (1927) saw only one case of chorea in his consulting practice in 700 consecutive cases between the ages of 6 and 10 years. Chorea is three times as common in girls as in boys. Still (1912) attributes this to the greater nervous instability of girls, and here few will be found to disagree. This remarkable disparity in sex incidence is not shown by rheumatic arthritis or carditis.

The Relation of Chorea to Rheumatism

The facts concerning the relationship of chorea to rheumatism may be concisely stated. They are that (1) rather more than one-quarter of all rheumatic children enter the rheumatic state by way of chorea; (2) in addition, another quarter of all rheumatic children develop chorea at some time in the evolution of their rheumatism; and (3) a number of children with chorea, estimated by various authorities to be between one-third and one-half, never develop any rheumatic episode.

These facts mean that chorea is a frequent associate of the rheumatic state in children. In some children the choreic state never progresses to rheumatism; in others the chorea precedes the rheumatic state by weeks, months, or years; while in others chorea develops during the phase of acute rheumatism or at some time after it. The inference from these facts is that the effect of the rheumatic inflammation on the cerebrum of a predisposed child is of exactly the same nature as the effect of prolonged emotional strain or acute psychic trauma. It is suggested that all these factors operate by heightening an emotional and kinetic instability which is already present in the child. It is apparent that the association of chorea with rheumatism is without parallel in clinical medicine. The profound difficulties in understanding this association come near to solution if the rheumatic state is regarded as a unique disorder with two components—nervous instability on the one hand and an inflammation of the heart and joints on the other. Both of these components may occur independently, but either, in some unexplained way, favours the development of the other. In any case the facts concerning chorea do not support any theory that chorea is directly due to the rheumatic "invader" or to "rheumatic toxaemia." It may be regarded either as a prelude to the rheumatic state or its accompaniment; but frequently, and fortunately, it is neither the one nor the other.

Chorea, then, may be defined as a functional disorder of the nervous system, characterized by irregular motor activity and emotional instability, which develops in predisposed individuals, particularly girls of the poorer classes, following acute psychic trauma or prolonged psychic stress, or during and after the development of the rheumatic state.

(To be concluded. A list of references will appear at the end of Part II)

The Minister of Health announces (Circular 2734) that he has had under review the arrangements for the supply of insulin free or at a reduced price to persons suffering from diabetes. Under the National Health Insurance Acts an insured person entitled to medical benefit may obtain insulin free if it is prescribed or dispensed by his insurance doctor. Insulin may also be provided as part of medical relief for any destitute person under the Poor Law Acts. As regards school children, in a few cases the Board of Education has in the past sanctioned the supply of insulin free or at a reduced price where the parents could not afford the whole cost. This sanction is now extended so that all education authorities may, for the duration of the war, supply insulin free or at a reduced price to all children at elementary schools or at institutions for higher education. The needs of other persons for whom there is no public provision apart from poor relief, such as dependants of insured persons, widows and spinsters engaged in household duties, and merchant seamen on foreign-going ships, are to be met by a wider use of the powers given to local authorities under the Public Health Act, 1936, temporarily to supply medicine to the poorer inhabitants of the district. The Minister now gives the necessary consent to the supply of insulin to such persons for the duration of the war.

A CASE OF WEIL'S DISEASE IN AN ARMY CAMP

BY

Capt. S. VARADI, M.D.

From an E.M.S. Hospital

In the last few years numerous articles on leptospirosis icterohaemorrhagica have been published in this country. The cases were either sporadic or occurred in endemics in certain occupations (sewer labourers, fish-workers, coal-miners, etc.).

The first authentic record was that of Manson-Bahr *et al.* (1922). In 1923 an epidemic of jaundice in coal-pits in East Lothian was described by Gulland and Buchanan (1924). In 1934 Hamilton Fairley reported cases of leptospirosis among sewer labourers in London. Swan and McKeon in 1935 recorded 12 cases among coal-miners in Northumberland and Durham, to which they added 17 others in 1938. Davidson and Smith in 1936, describing Weil's disease in fish-workers, gave a detailed account of its clinical manifestations. Willoughby and Shera (1934), Watson, McLeod, and Stewart (1935), Maxwell (1935), Wolstencroft (1935), Halsted (1935), Neale (1935), Alston (1935), Lendrum (1936), and Stuart (1938) each describe a case of Weil's disease. Alston and Brown have reported several cases in sewer-workers. In 1936 cases among soldiers bathing in the Basingstoke canal in the Aldershot district were published. Kenneth Robertson (1938) reported 4 cases of Weil's disease infected from the same stream. This short review does not claim to be complete.

Case Report

Soldier aged 22, admitted to hospital March 31, 1942. Previous history: At age of 6, pneumonia, measles; 1939, fracture of os calcis. The history of the present illness was as follows. March 28, 1942, in the morning felt "cold running down his back" on several occasions. At noon was giddy, went to bed, and slept the whole afternoon. In the evening he had several attacks of shivering and sweated freely. On attempting to rise his legs felt weak, and after some steps he was compelled to lie down again. Vomited. Sleepless at night because he felt very hot and had agonizing pain in legs. Following day remained in bed; refused food; was feverish whole day. Had to be helped to lavatory; complained of stabbing pain in knees, severe pain in calves, and a feeling as if knees would give way. From time to time had gripping pain in stomach, and nausea. In the evening seen by M.O., who prescribed some cachets. Restless night. March 29: afternoon temperature 102.4° F.; 30th: morning 99.3° F.; afternoon 103.3° F. Noticed difficulty in breathing deeply on account of catching pain below the costal margins. Stools normal. The patient was living in a camp which was infested with rats. Although he did not on any occasion come into actual contact with a rat, he did handle a rat-trap.

On admission, March 31, 1942, he complained of weakness and continuous pain in his legs, increasing at any attempt to get up ("as if someone was cutting through his muscles with a knife"). Loss of appetite. Micturition normal. T. 100.2–101–100° F. Skin moist, hot, slightly jaundiced. Herpes facialis at right angle of mouth. Slight congestion of conjunctiva of eyelids and eyeballs. Tongue slightly coated with white fur. Mucosa of soft palate, tonsils, and uvula congested; uvula slightly oedematous. Forcible pulsation of carotid arteries. Lungs and heart, N.A.D. Pulse 96, regular. Tenderness in right upper abdomen on pressure; no guarding, no mass palpable. Spleen and liver not palpable. Muscles of both calves extremely tender on pressure. The patient lacked the strength to lift his legs from the bed. The muscle tone was greatly diminished in both limbs. Knee and Achilles tendon jerks almost absent. Plantar reflex normal. Urine: Dark yellowish-brown; albumin ++; urobilinogen +++. Deposit: Very scarce red and white cells; no casts; some round epithelial cells, and several large epithelial cells containing bile pigment and showing degenerative changes.

April 1.—T. 101–99.1–101.5–100° F. Headache. Slight rigidity of neck; conspicuous jaundice. Urine: Albumin ++; bilirubin +; urobilinogen +++. Deposit: Numerous granular and hyaline casts; few R.B.C. and round epithelial cells.

April 2.—T. 99.2–97–99–98.4° F. Jaundice intense; orange-yellow colour. Conjunctivae very congested; pink eyes. Pains in eyes and headache. Tenderness in right upper abdomen persisting; tenderness of calves decreasing. Vomited several times. Felt very weak. Herpes spreading with haemorrhagic crust. Tongue: thick dry grey-brown fur. Capillary resistance test, negative. B.P., 90/50; pulse 68; blood urea, 100 mg. per 100 c.cm.

April 3.—T. 99–97.8–99.2–99° F. Complained of intense itching of skin. Small petechiae on sides of thorax and abdomen. Morbilliform rash over loins, sides of abdomen, and below scapulae; symmetrical distribution. Knee- and ankle-jerks: L. absent, R. very diminished. Tenderness of muscles of right arm. B.P., 95/55; urine scanty—1 c.cm. Cheeks sunken. Throat dry.

April 4.—T. 99.7–97–98.9–98.4° F. Agglutination with *L. icterohaemorrhagiae,* 1: 320. No leptospira found in urinary deposit. Patient drowsy. Rash gone. Pink eyes. Intense itching of skin. Petechiae on sides of thorax and abdomen. Sputum blood-stained. No leptospira found in sputum.

April 5.—T. 98.5° F. (max.). Passed fair amount of urine after sod. bicarb., pot. citrate, āā 30 gr. 2-hourly, and hypertonic glucose.

April 6.—T. 98.2° F. (max.). Patient drowsy. Cheeks sunken. Tenderness localized to gall-bladder area. Hard axillary and inguinal glands of pea and bean size. Sputum still blood-stained. Calf tender on left side. Urine: Trace of albumin.

April 7.—T. 98.4° F. (max.). Acid fetor ex ore. Pink eyes. Jaundice still very marked. No leptospira found in urinary deposit (stained Giemsa: Fontana's stain not yet available). Sternal puncture did not reveal leptospira.

April 8.—T. 98.3° F. General condition slightly improved.

April 9.—T. 97.9° F. Less jaundiced. Few blood specks in sputum. Herpes disappearing. Tongue coated but moist. Photophobia.

April 10.—T. 98° F. Patient less drowsy; felt better. Jaundice decreasing, as well as the hyperaemia of conjunctiva. Gall-bladder area still tender. Numbness in lower limbs.

April 11.—T. 98.9° F. Tongue almost clean, moist. Felt much better. Although jaundice less, had intense itching all over the skin Slight tenderness in gall-bladder area. Agglutination with leptospira, 1: 4000.

April 13.—T. 98.8° F. Almost complete absence of skin sensitivity to touch and pain over left leg and thigh—very slightly impaired on right side. Absence of skin sensitivity to heat over both legs and left thigh; diminished sensitivity over right thigh. Ankle-jerks present. Left knee-jerk absent, right diminished. Had paraesthesia below knees.

April 15.—T. 98.5° F. Knee-jerks absent, ankle-jerks present. Skin sensitivity over left limb reappearing, over right leg impaired. Vibration sense absent over right leg, present over left. Urine: No albumin. Deposit: A few granular casts, round epithelial cells, urethral epithelial cells, leucocytes, amorphous urates. All stained with bile.

April 16.—T. 99.2° F. Epistaxis. Knee-jerks returning. Skin sensitivity to heat reappeared over right leg; tactile sensitivity still impaired. Vibration sense normal.

April 17.—T. 99.2° F.; April 18, 98.6° F.; April 19, 99° F.

April 20.—T. 97° F. Complained of itching of skin. Jaundice slight. Skin sensitivity normal. Knee-jerks diminished (especially right).

April 24.—T. 98.4° F. Glands still enlarged.

April 27.—T. 98.8° F. Leptospira found in urinary deposit in fair amount (stained by Fontana's method). No albumin.

May 4.—T. 98.6° F. Urine: Trace of albumin. Knee-jerks diminished but present.

May 8.—T. 98.5° F. Urine: Trace of albumin. Deposit: Scanty granular casts, epithelia. No spirochaetes seen (Fontana's method).

May 9.—T. 98.7° F. Urine: Albumin present.

May 10.—T. 98.6° F. Urine: Albumin present. Glands almost entirely normal.

May 14.—T. 98° F. Urine: Trace of albumin.

May 15.—T. 97.3° F. Urine: Albumin absent. Deposit: A few leucocytes and epithelia from lower part of urinary tract. Few hyaline casts and pseudocasts.

May 28.—Patient felt well. Complained only of very slight general weakness. During last 6 weeks losing hair.

June 15.—Discharged to convalescent home.

The patient made an uninterrupted recovery.

Discussion

From a clinical point of view this was almost a classical case, showing most of the characteristic features of the disease. I would like to draw attention to the localization of the rash that appeared on the 7th day of illness and its quick disappearance. For these two reasons it could easily have remained undetected. There was a rather extensive involvement of the nervous system. In the first day or two there were signs of slight meningeal participation (neck rigidity), which subsided rapidly.

The knee- and ankle-jerks were practically absent from the day of admission (4th day). The ankle-jerks reappeared within

12 days, the knee-jerks in about a fortnight. There was an almost complete absence of skin sensitivity to touch and pain (pin-pricks) over the left lower limb, and impaired sensitivity over the right one. (It is possible that previously the right side was more affected.) The sensitivity to temperature and the vibration sense were both involved. These sensory troubles subsided at about the same time as the tendon-jerks were returning. Paraesthesia was present in the legs. I am indebted to Major-Gen. Priest for having drawn my attention to these sensory changes, which were most probably due to a polyneuritis. Lendrum, Alston, and others report absence of tendon-jerks in their cases. A detailed account of nervous complications of Weil's disease is given by Vagn Mortensen.

Our case is a further proof that whenever an acute febrile illness appears, associated with nephritis, severe muscular pain, and great tenderness in the muscles of the limbs, one must consider the possibility of Weil's disease. And if the interrogation of the patient proves that there was a possibility of infection by rats, serum treatment should be at once introduced, without waiting for the laboratory confirmation of the diagnosis. The highly beneficial result of this treatment, if started in the pre-icteric stage, has been confirmed by Schüffner, Kenneth Robertson, and others.

As to the source of infection of the present case it is interesting to note that there was no contamination by any of the ways commonly described. The patient was a young soldier living in a camp in the country. At the time of the year there was no bathing, and had it been an infection of the water source several cases would have been expected from the same unit. The only other case of febrile illness with headaches and very slight pains in the lower limbs, but without nephritis or jaundice, serologically did not prove to be a leptospiral infection. The camp where the patient was living, and especially the neighbourhood of the stores where he was working, was infested by rats which he and his comrades used to "hunt." The patient used to handle a rat-trap, and very probably was infected by the animals' excreta on the trap. He had no abrasions on the skin of his hands; therefore, infection was most probably via one of the mucosae contaminated by his fingers.

Owing to the war, the laboratory investigations were limited to the minimum. Thus, blood urea tests were made only once, on the 6th day of illness (100 mg. per 100 c.cm.). At the height of the uraemia this figure would have undoubtedly been higher. There were no reports about the degree of bilirubinaemia.

Fairly detailed haematological examinations were performed by me. The red cells during the peak of the jaundice—from about the 7th to the 17th day of illness—showed a marked macrocytosis. There were a few R.B.C. with punctate basophilia. The slight degree of anaemia at the end of the 3rd week (80% Hb; 4,045,000 R.B.C.) disappeared in the 4th week (85% Hb; 4,810,000 R.B.C.). The number of W.B.C. increased from 13,350 on the 4th day to 21,150 on the 13th, returning to normal figures (7,800) on the 28th day of the disease.

Whereas at the beginning only the neutrophils accounted for the leucocytosis, from the end of the second week the lymphocytes were also participating in it. After the return of the neutrophils to their normal figures the lymphocytosis continued. During the period of neutrophilic leucocytosis there was a shift to the left from the 11th to the 13th day, with a very noticeable number of metamyelocytes and myelocytes. In view of the good recovery of the patient we can refute the claim made by some haematologists that this is a bad prognostic sign in Weil's disease. During the stages of leucocytosis there were toxic changes of medium degree in a part of the neutrophils, such as coarse irregular granules, basophilic inclusions and vacuoles of the cytoplasm, and slightly "toxic" nuclei. Eosinophils were never completely absent, and during the jaundice and the recovery stages there was sometimes an eosinophilia. The sternal puncture showed changes usual in infective conditions with neutrophil leucocytosis.

Bacteriology.—When chemicals for the Fontana stain were provided I succeeded in demonstrating the leptospira in the urinary deposit on the 33rd day of illness. No leptospira were found after the 40th day. For the bacteriological investigations of the case I am indebted to Dr. Nancy Laughton of the Department of Bacteriology, University of Birmingham. Her report of May 11, 1942, was as follows:

> "Three specimens of urine were inoculated intraperitoneally—those of the 8th, 12th, and 20th days of the illness. The animals inoculated with the first and the last showed no illness. The former is still apparently healthy. The latter showed no sign of illness or jaundice. It was killed on the 10th day: the necropsy revealed no evidence of infection. Portions of the liver and spleen were macerated and reinoculated into another 6-weeks-old guinea-pig. This animal appears quite well after 14 days.
>
> "The guinea-pig inoculated with the 12th-day urine died on the 12th day after inoculation. The necropsy revealed marked jaundice. The peritoneum was thickened, the suprarenals were congested, and there were marked haemorrhages into the lungs.
>
> "Although we were not able to recover the living organism by cultural methods, sections of the liver and kidney stained by Levaditi's method show a large number of leptospira."

The blood serum agglutinated *L. icterohaemorrhagiae* 1:320 on the 8th and 1:4000 on the 15th day. Further specimens were not examined.

Treatment.—This was purely symptomatic, as the patient was admitted on the 4th day of the disease, when the urine examination already revealed a great increase in urobilinogen. Serum would have taken too long to obtain for it to be of any appreciable value in treatment. From the first day the patient had rich glucose drinks, and at the peak of the disease glucose intravenously and glucose-saline as intravenous drip infusions, together with pot. citrate and sod. bicarb. āā 30 gr. 2-hourly. From the 10th day the patient had hexamine 10 gr. t.d.s. The bowels were moved by enemas and magnesium sulphate. We cannot form any opinion of the effect of sulphapyridine given on the 4th and 5th days of illness in a total dose of 5 g.

From this case once again it is evident that we have to reckon with the possibility of Weil's disease occurring whenever wild rats are present (25% of all rats in this country are infected—Hurst, 1940). The means of infection are numerous, and these have been described in many excellent publications. I would merely like to point out the necessity for the systematic extermination of rats, especially in Army camps, where they usually swarm in the proximity of cookhouses and stores if not destroyed in time. Persons dealing with the destruction of rats should be made aware of the danger they run when handling objects that might have been soiled by the dejecta of these animals.

Summary

The case of a young soldier who contracted Weil's disease while handling a rat-trap is reported.

Apart from a typical clinical picture a marked involvement of the nervous system was present.

Leptospira were found in the patient's urine and in the kidneys, liver, and adrenals of the guinea-pig inoculated with the patient's urine.

Agglutination with *L. icterohaemorrhagiae* gave titres of 1 : 320 and 1 : 4000 on the 8th day and the 15th day respectively.

I wish to thank Dr. D. R. Rigg, medical superintendent of the hospital, for his interest and permission to publish the case.

Irvine H. Page and others (*Amer. J. Physiol.*, 1941, **135**, 214) show that the liver is the chief source of renin activator. In the case of removal of or damage to the liver by toxic substances, there is no pressor response to injected renin.

THE INACTIVATION OF PHOSPHORUS ON THE SKIN

BY

M. W. GOLDBLATT, M.D.Belf., B.Sc., Ph.D.Lond.

AND

S. H. OAKESHOTT, B.A., B.Sc., D.Phil.Oxon.

Imperial Chemical Industries (Dyestuffs) Limited

White phosphorus as a hazard may appear in a variety of physical forms. Of these the most important are: (1) solid, (2) dissolved in solvents (CS_2, benzene, mineral oil), (3) dissolved in solvents + rubber. The use of copper sulphate solutions for the inactivation of phosphorus on the skin has long been practised, and has been suggested by the Ministry of Home Security (1942) as a method in the case of burns from bombs containing phosphorus. An improved composition in which copper sulphate is dissolved in aqueous glycerol has been claimed by Godding and Notton (1942). The very high glycerol content in this preparation is a serious drawback to its general use in the event of the widespread use of phosphorus bombs. An examination of the question of inactivation of phosphorus in the conditions listed above has drawn attention to the limitations of the methods hitherto proposed. We now describe a preparation of our own which has certain advantages.

According to the form in which the phosphorus is present on the skin, the aim of treatment is:

For solid phosphorus, to coat the element with a non-ignitable layer and to render large particles visible and thus amenable to mechanical removal; in the case of minute particles, to convert the element completely to an inactive form, allowing of removal by washing.

For phosphorus in solution, to inactivate the element by means of an agent which mixes freely with the solution or which brings about efficient emulsification, allowing of intimate contact with the inactivating agent.

For phosphorus in solvents containing rubber, to inactivate the element in the highly viscous mass by means of an agent which permits ready emulsification and which, in addition, allows complete removal of the rubber from the skin.

Copper compounds in a suitable physical form can bring about all of these desired effects.

Mode of Action of Copper Compounds on White Phosphorus

Whilst the blackening which rapidly follows the application of copper salts to white phosphorus is commonly held to be due to the formation of non-igniting copper phosphide, this is not the whole story. Copper phosphide is certainly produced, but this is followed by a reaction leading to the formation of various phosphorus acids—mainly phosphoric—and metallic copper (see Straub, 1903; Bird and Diggs, 1914). The main reaction is the formation of metallic copper, as follows:

$$5Cu^{\cdot\cdot} + 2P \rightarrow 2P^{\cdot\cdot\cdot\cdot\cdot} + 5Cu$$

Thus, if $CuSO_4$ is used, a necessary accompaniment of the reactions is the formation of sulphuric acid and phosphoric acid, which adds to the acidity already present if the phosphorus has ignited. The consequent need for thorough alkalization has been stressed by Godding and Notton (1942) and Jones (1942).

In the circumstances in which aqueous copper sulphate would be used in inactivating solid phosphorus in a burnt area nothing like complete inactivation of the element could be obtained. If, further, the phosphorus is in a form with which water does not readily mix, then inactivation can be expected only at the interfaces of the two liquid phases. In the special case of incendiary-bomb compositions, of a highly viscous nature, the application of aqueous copper sulphate cannot be expected to be effective. Godding and Notton's mixture was devised to overcome this difficulty and, as we shall see, is a distinct advance, but it has the disadvantage of demanding considerable glycerol and not acting very effectively on solid phosphorus or phosphorus in solution (CS_2, benzene, oil).

If an incendiary mixture containing rubber dissolved in a solvent be smeared on the skin the rubber adheres to the skin and in a few moments white fume appears but there is no rapid ignition. If now Godding and Notton's mixture be applied and rubbed well in, a greenish mass is formed, slowly turning brown and staining the skin. With continued rubbing the rubber in the composition is in part detached, but the greater portion of it is not readily removable, and may contain active phosphorus. If the incendiary composition is treated with Godding and Notton's mixture on a watch-glass reaction is rapidly initiated, but to obtain complete inactivation it is necessary to continue to mix energetically for a considerable period.

A New Preparation for Inactivating Phosphorus

Having regard to the fact that phosphorus is essentially lyophilic in nature and thus not readily wetted by water, it appeared to us that the reaction of inactivation might be hastened by the presence of a fat-solvent, using the copper in an oil-soluble form. If, further, the solvent used were capable of dissolving rubber a marked advance might be expected. Such a mixture has been devised. It consists of copper oleate, trichloroethylene, Turkey-red oil (70% ammonia-finished), and surgical spirit, and is prepared as follows: 25 g. copper oleate, is dissolved in 35 g. trichloroethylene; 25 g. of Turkey-red oil (sulphonated castor oil, 70% ammonia-finished) is incorporated into the mixture, after which 15 g. of surgical spirit is added. The copper content of this solution may reach 2.5%, but varies according to the quality of oleate. The presence of the alcohol cannot be dispensed with in cases of compositions containing rubber; but in other circumstances (e.g., phosphorus as an industrial hazard) it may with advantage be omitted.

This solution is readily prepared (Godding and Notton's mixture is not easily prepared), is perfectly homogeneous, and is deep blue-green in colour; it is a solvent for rubber and is easily emulsified with water. The constituents are available.* Its effects on phosphorus in various forms are summarized in the following table of comparison with other preparations:

Form in which Phosphorus is Present	1% $CuSO_4$ Aqueous Solution	$CuSO_4$, Glycerol, and Starch Mixture of Godding and Notton	Oil-soluble Cu Preparation
Solid	Rapid surface inactivation only	Very slow surface inactivation	Very rapid inactivation, with disintegration of the surface layers
Solution in CS_2	Inactivation at interface only	Inactivation at interface	Rapid and complete inactivation
Solution in benzene	" "	" "	" "
Solution in liquid paraffin	" "	More rapid inactivation due to some emulsification	" "
Solution in benzene and rubber	Poor and incomplete owing to lack of emulsifying properties	Very rapid and complete if well mixed, due to good emulsification	Rapid and complete inactivation. The reaction, once started, proceeds to completion with great speed

Advantages of the New Method

The following are the advantages of the new preparation: (1) It is readily miscible with oil, being dissolved in an oil-solvent which is also a solvent for rubber. This allows intimate contact with white phosphorus as well as with any oily composition in which phosphorus may be dissolved—e.g., in an incendiary bomb or other weapon. (2) It reacts progressively with phosphorus, not merely inactivating the surface of contact but transforming the element into easily removable products. (3) Since the preparation contains its own emulsifying agent (Turkey-red oil), it is completely removed from the skin by water, carrying with it any oil or rubber that may have been associated with the phosphorus, as well as the detritus from the inactivating reaction. The skin is left almost entirely clean and unstained.

---

* Copper oleate is a commercially available material, but in case it cannot be obtained, an equally effective material (although of lower copper content) can be prepared in the following way: Copper sulphate (10 g.) is dissolved in hot water (40 c.cm.) and 70% Turkey-red oil, ammonia-finished (25 c.cm.), added, with stirring. An insoluble copper derivative separates, and after cooling is decanted from the water. The oily copper compound is dissolved in trichloroethylene (35 c.cm.) and any remaining water separated off. A further addition of 70% Turkey-red oil (25 c.cm.) is made, and finally surgical spirit (20 c.cm.).

Anaesthetized rats were treated, after dehairing, with a few drops of white phosphorus dissolved in CS_2, and, after allowing the solvent to evaporate, the layer of phosphorus was inactivated by application of the above copper preparations. There was considerable difficulty in applying the 1% copper sulphate aqueous solution, since the rat's skin and the phosphorus layer are alike difficult to wet with aqueous solutions. The copper–glycerol mixture was better in this respect but reacted slowly compared with the oil-soluble copper preparation. Minute pieces of phosphorus applied to the skin were rendered inactive by the oil-soluble copper solution and disintegrated, while the copper sulphate solution and the copper–glycerol mixture rendered them inactive but left them entire. Here again the 1% copper sulphate reacted more quickly than the copper–glycerol once it had been brought into intimate contact with the phosphorus.

Phosphorus applied to the skin either alone or in solution in CS_2 appears to have no immediately deleterious action. Its danger resides wholly in its liability to ignite and cause burns which do not easily heal. This point was shown not only by animal experiments but by application to the human skin. Phosphorus allowed to ignite on the skin (after evaporation of the CS_2 in which the phosphorus was dissolved) is immediately extinguished by the oil-soluble copper preparation, and inactivation of the phosphorus begins almost at once.

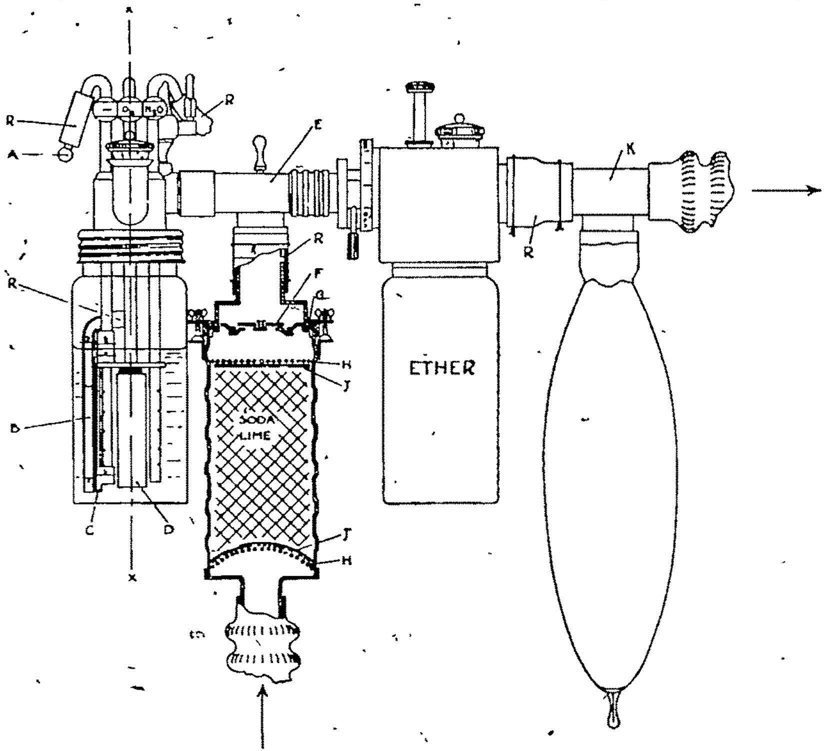

FIG. 1.—Front view; CO_2 absorber in section. A, Plug. C, Scale B, Magill's bag-mount. R, Rubber connexions. (Other reference letters explained in text. Scale of drawings, 1/4 size)

Proposed Procedure for dealing with Phosphorus on the Skin

1. Extinguish burning areas (immersion in water or wet fire-blankets).
2. Apply oil-soluble copper compound to areas contaminated with phosphorus (swabbing, pouring over areas, in some cases even immersing affected parts: manner of application will suggest itself according to circumstances. In general it will be best to deal with the affected parts piecemeal while keeping the waiting parts wet with water).
3. After well-established and obvious inactivation of the phosphorus (in general, in from a few seconds to one or two minutes), wash the treated area with tepid water and swab off the contaminating material.
4. Treat area with excess sodium bicarbonate, working up into a paste with water.
5. Treatment of the burn itself will naturally depend on circumstances, but if all the phosphorus is inactivated and removed and all acidity is neutralized, accepted methods on the lines of antisepsis and mild tanning should be applicable. The location of the burn, its depth, and the amount of tissue destroyed must all be considered in the treatment. General rules for all cases are misleading.

Summary

The phosphorus-inactivating properties of 1% aqueous copper sulphate, the copper sulphate–glycerol–starch composition of Godding and Notton, and a new composition containing copper in an oil-soluble form made from copper oleate, Turkey-red oil (sulphonated castor-oil), trichloroethylene, and surgical spirit have been compared. The last is shown to be the most effective way of inactivating phosphorus, especially when associated with oil, solvents, or rubber. A procedure is suggested for dealing with cases contaminated with material from self-igniting bombs containing phosphorus, oil, solvents, and rubber.

N.B.—It must be pointed out that the treatment proposed is for phosphorus *on* the skin. The high content of trichloroethylene precludes use of the composition for such internal injuries as were recently described by Blaxland (1942), in which elemental phosphorus was diffusely implanted in the tissues.

MODIFICATION FOR CO_2 ABSORPTION WITH THE FIELD-PATTERN BOYLE'S APPARATUS

BY

J. MONTGOMERIE, M.B., D.A.
Major, R.A.M.C.; Anaesthetist to a General Hospital

With the object of effecting economy of gases I have devised a modification of the field-pattern Boyle's apparatus by which carbon dioxide absorption may be used. This has proved to be very satisfactory in practice. The essential additions are a flowmeter for "basal" oxygen and a soda-lime canister. A description of these improvisations is given in the hope that it may be of use to other anaesthetists.

The Flowmeter

The flowmeter (Figs. 1, 4, and 5) was designed to fit inside the sight-feed bottle, and is of the water-depression type. Its design was restricted by the limited space available. The oxygen cylinder is connected to the middle sight-feed tube, CO_2 not being used. Oxygen thus passes to the top of the bottle by way of the metal sleeve and tube (D), and escapes through a glass capillary (M). T indicates a connexion to the glass depression tube (B). The scale was cut from zinc-alloy sheet, and is wired to the normal oxygen sight-feed tube. Calibration was carried out by timing the displacement of water from a large measuring bottle. Preliminary experiments determined the proper size of capillary tube to obtain the desired range—200 to 650 c.cm. a minute.

Nitrous oxide is run in through the normal sight-feed tube.

The Carbon Dioxide Absorber

The canister was improvised from a training-model Service respirator container (Fig. 1). The bottom (inspiratory valve end) was unsoldered and fitted as a lid by attaching lugs to receive bolts fixed to the body. There are four of these, only two showing in the section. A rubber washer (G) ensures a gas-tight joint. A flat metal cylinder and a short length of 1-in. tube soldered over the hole in the lid enables a connecting tube to be attached. All the contents of the container were removed and two of the pieces of metal gauze (H) with lint pads (J) used to retain the soda-lime, 1 lb. of which can be accommodated. The unfilled space of about 1 in. at the upper end is important to avoid "channelling."

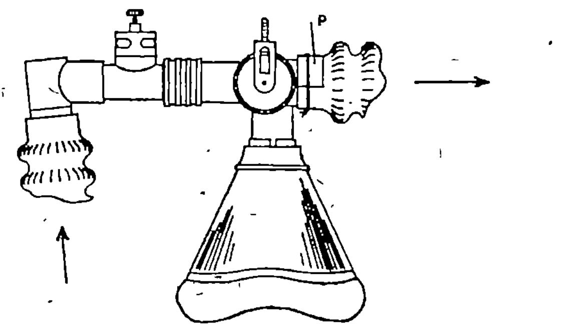

FIG. 2.—Arrangement of face-piece fittings: P, Tin strip over slot in stopcock.

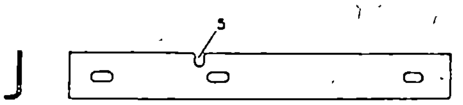

FIG. 3.—Detail of extension bracket. S, Slot for handle of bag-mount valve when closed.

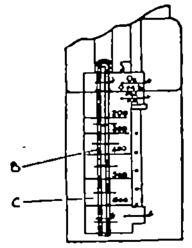

FIG. 4.—Side view of flowmeter, showing scale.

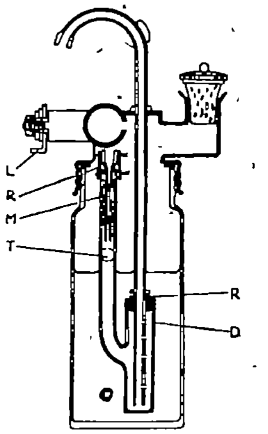

FIG. 5.—Section of flowmeter.

Arrangement of Apparatus

The arrangement shown in Fig. 1 works on the "circle" principle and permits vaporization of ether by the expired gases. The absorber is connected to the Magill bag-mount which is fitted between the ether bottle and flowmeter. The latter is supported by an extension bracket cut from brass sheet (Fig. 3, and L, Fig. 5). The bag is mounted on an improvised T-tube (K). One-way gas flow is attained by incorporating the stopcock from a nitrous oxide-air apparatus, with the cap over the expiratory valve removed, in the face-piece fittings (Fig. 2). The inspiratory valve of the respirator (F) is fitted, as shown in Fig. 1, to prevent back-flow of gases into the absorber when it is not in circuit. This assembly results in some expiratory resistance, due to the by-pass control on the ether bottle. With quiet breathing the pressure at the mask is not excessive, being between 2 and 3 mm. Hg; but an appreciable increase occurs with deep breathing and if the gases are bubbled through the ether.

Two alternative arrangements may be used. In the first, the flowmeter and ether bottle are left in their usual positions and the absorber is fitted between the ether bottle and the rebreathing-bag. In the second, the canister is fitted near the face-piece and "to-and-fro" absorption is used. Both alternatives overcome the expiratory resistance, but ether vaporization is dependent on the small "basal" flow of gases only.

Additional corrugated tube is improvised from the respirator connecting tube. All rubber connexions are secured by binding with wire. The materials used are easily obtainable in the field, and constructional work can be carried out by the nearest workshop unit. It will be noted that the Boyle apparatus is not altered structurally.

Notes on Technique

(1) Adequate sedative premedication is desirable.

(2) A full anaesthetic dose of pentothal sodium, followed by nitrous oxide-oxygen with this apparatus, has been very successful.

(3) When an intravenous anaesthetic is not used, induction is most satisfactorily carried out by the "semi-closed" method, CO_2 absorption being started when surgical anaesthesia is well established.

(4) Owing to the diffusibility of nitrous oxide it is seldom possible to discontinue its flow completely, and about 500 c.cm. a minute is required for maintenance.

(5) The composition of the gas mixture tends to change slowly during the course of the anaesthesia. As with nitrous oxide-oxygen a fine balance is struck between anoxia and the patient becoming "lighter," this is important, and is best overcome by periodically emptying the bag and refilling with the appropriate mixture.

A NEW CIRCLE-TYPE CARBON DIOXIDE ABSORBER

BY

WILLIAM W. MUSHIN, M.B., B.S., D.A.

Honorary Anaesthetist, Seamen's Hospital, Greenwich, and Central London Throat, Nose, and Ear Hospital; Anaesthetist, Royal Dental Hospital; Anaesthetist, E.M.S.

With the collaboration of Messrs. Coxeter and Son, Ltd., who initiated this endeavour, a circle-type absorber with certain unique features, and in which anaesthetic requirements have been combined with mechanical efficiency, has been produced. The aims of its design and the way these aims have been achieved are as follows.

The machine was specifically intended to fit the standard Boyle machine that has been distributed widely in the E.M.S. It slides on two runners fixed to the table frame, and can be pushed under the top shelf when not in use. Minimum restriction to breathing was achieved by using wide-bore gas channels throughout, and making the patient's respirations take a path with as few changes of direction as possible. Large control drums are used and special glanding arrangements provided to eliminate leakage. In the ether vaporizer, wicks, which to be effective need several thicknesses and which soon cause restriction, have been eliminated. The moving parts of the reservoir bag are carefully balanced on ball bearings, and move with the slightest respiratory effort. The measured restriction of the circuit is 2 mm. H_2O with the ether and soda-lime "off" and 4 mm. H_2O with both "on."

High-efficiency absorption of CO_2 was achieved by departing from the orthodox type of circuit and employing one in which both inspirations and expirations pass through the soda-lime, thus combining the absorptive efficiency of the "to-and-fro" type with the practical advantages of the "circle-type" absorber.

The type of ether vaporizer normally used in an absorber circuit has a wick to give sufficient surface of contact of the ether to provide a high enough concentration of ether in the mixture. The disadvantage of this type is the restriction caused by the wick and the gradual loss of efficiency due to condensation of water on the wick. Both these disadvantages are overcome in this vaporizer by dispensing with the wick and, instead, causing the gases to be deflected by baffles several times on to the surface of the ether. By bringing the gases into the vaporizer at the centre of a concentric nest of baffles the lowest ether temperature is reached at the centre of the container. The temperature drop in the peripheral portions of the ether is at a minimum, and the gases before leaving the vaporizer are in contact with the warmest possible ether. The baffles, like the ether pot, are made of copper, and act as conductors of heat from the rest of the apparatus to the liquid ether.

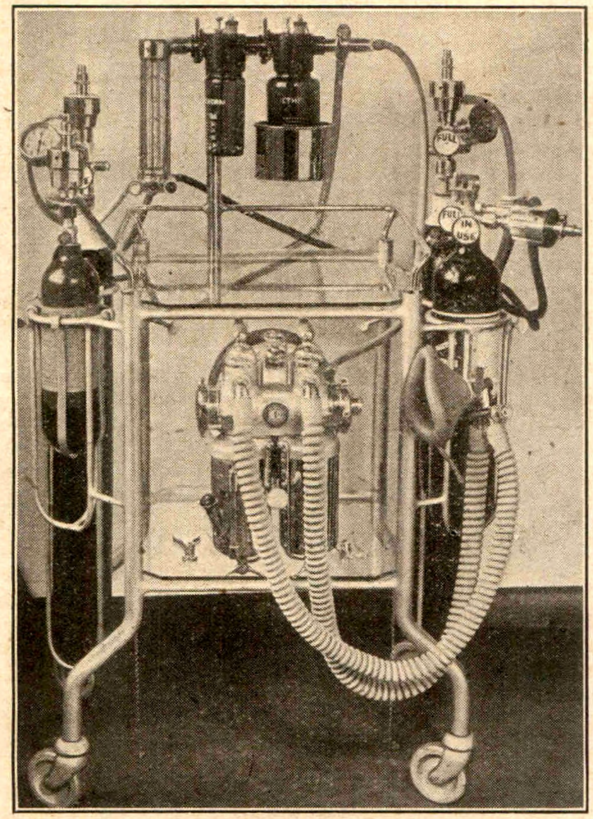

FIG. 1.—Boyle machine with absorber in place.

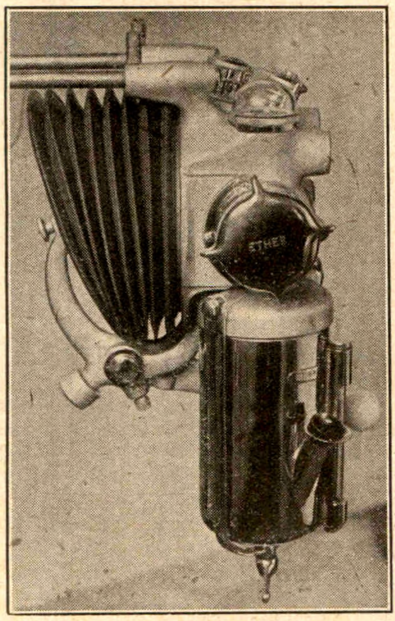

FIG. 2.—Side view of absorber showing bag and lever mechanism.

To make inflation of the lungs easy, whether for control of the respiration or for the purpose of artificial respiration in emergency, the bag is of concertina shape. It is connected to a lever ending in a conveniently placed knob on the front of the machine. Depression of this knob compresses the bag with little effort on the part of the anaesthetist. The lever system is carefully balanced on ball bearings so that the bag moves with the slightest respiratory effort.

Other features of this absorber are: (1) The body of the machine is cast in one piece with the drum channels bored in it, to avoid leakage. (2) The slightest movement of the bag is transmitted to the knob, which can be easily seen. (3) Both expiratory and inspiratory valves are fitted on the machine, as well as a nipple through which air can be introduced. (4) The soda-lime canister is quickly removed by swinging aside a large easily loosened sling. (5) The gravity valves are made of scolam, a compressed fibre which allows them to be twice as thick as metal, thus lessening the possibility of warping, without increase of weight. These valves are visible, and in wartime are easy and cheap to replace.

Several of my colleagues have given a clinical test to this absorber, and for their helpful suggestions I am most grateful. They have confirmed my opinion that only as a result of collaboration between manufacturers and user can a real advance in the design of anaesthetic apparatus be made. A detailed account of this machine with the results of laboratory and clinical tests will be published shortly.

Medical Memoranda

Spina Bifida in Binovular Twins

In view of the rarity of spina bifida in twins and of the absence in the literature of any reference to its occurrence in binovular twins, the following case may be of interest.

CASE HISTORY

Mrs. B., a healthy 3-para, had had a normal pregnancy and was due to be confined about July 4, 1942. Labour started on May 28 about 11 p.m. The first twin was born at 12.40 a.m. on May 29 and the second ten minutes later. Both were males, and there was rather a large amount of liquor amnii. The first infant weighed 4 lb. 12 oz. and was 16 in. long; it had an open spina bifida (without a sac) in the lower dorsal and lumbar region 2¾ in. by 1¾ in., with an associated hydrocephalus showing separation of the bones of the vault of the skull. The infant lived 33 hours. There was some leakage of cerebrospinal fluid. The second twin weighed 3 lb. 12 oz. and was 14 in. long; it also had a spina bifida without a sac in the lumbar region, 2½ in. by 1½ in.; the head was of normal size. There was also some leakage of cerebrospinal fluid. This infant became slightly cyanotic after a few hours and lived 36 hours. There were two separate placentae, which looked perfectly normal, and two chorionic sacs. There is no family history of twins or congenital abnormalities, and there was no history of any maternal trauma during pregnancy.

COMMENTARY

Spina bifida is described as a condition (*Gray's Anatomy*, 1938) in which the coalescence of the lamina is not completed: a cleft is left in the arches of the vertebrae, through which protrusion of the spinal meninges (dura and arachnoid), and generally of spinal cord, takes place. It is commonest in the lumbar and sacral regions; its frequency is given as about 1 in 1,000 births. A sac may be present or absent; in the latter case there is a leakage of the cerebrospinal fluid, which is incompatible with life. Spina bifida is often associated with congenital hydrocephalus (Boyd, 1938).

There were no definite records of the occurrence of spina bifida till the middle of the seventeenth century. Tulpius (1652) described a case in *Observationes Medicae*, Lib. III, **129/130**, p. 240. There are several theories of the causation of spina bifida. J. F. Meckel maintains that it is produced in some mechanical way, involving interference with the nutrition of the embryo (Good, 1915). Wertheim (1857) advances the theory of maternal impressions and external influences, and as a proof of this he quotes a case of twins one of which died early while the other showed a large spina bifida with the absence of the sacral and coccygeal vertebrae. The mother had received a kick in the left groin from her husband some weeks before the mid-term of gestation. Koch (1881) believes in the theory of arrested development. The London Clinical

Society committee appointed in 1885 to report on the origin of spina bifida gave as a cause the primary defect in the formation of mesoblast from which the structures closing in the vertebral furrow are developed.

Bland-Sutton (1888) advanced a theory in which he regarded the spinal cord as a highly differentiated section of the primitive alimentary tract. Its central canal was originally part and parcel of the system, but is now functionless and, like obsolete canals in general, is often the seat of cystic dilatation. The conclusion arrived at by Good is that it is the arrested development of the mesodermal tissues from which the spinal meninges are produced, and that it is due to a mechanical cause which prevents the neural plate becoming converted into a neural tube; there is no evidence as to the nature of this mechanical agent.

A few cases are on record of spina bifida occurring as a family defect. Butler-Smythe (1889) reports 3 cases of spina bifida with hydrocephalus occurring in the same family. Pybus (1921) describes a family in which 4 children had congenital defects of the spine. The eldest child died at 18 months with spina bifida associated with hydrocephalus; the second, 10 years old, had spina bifida occulta, indicated by a scar and depression in the upper part of the thoracic region of the spine, a radiograph of which showed a defect of the underlying vertebrae; the third had a meningomyelocele in the lumbo-sacral region, treated successfully by operation; the fourth child had an exaggerated coccygeal dimple.

The only case on record of spina bifida in uniovular twins is from Norway (Eskelund and Bartels, 1941). There are no cases on record of spina bifida in binovular twins.

The dizygotic origin of the twins in the present case is confirmed by the two separate placentae and chorions and the absence of striking similarity in the general appearance of the two infants, which is in conformity with the foetal-membrane method and similarity method of diagnosis of zygotic origin of twins (Newman, Freeman, and Holzinger, 1937). This case tends to support the theory that the cause of spina bifida is primarily a defect in the development of the mesoblastic tissues from which the spinal meninges are produced, as this is the only factor that is likely to affect equally the two separate ova, rather than the mechanical agent or the external influences mentioned in the several theories advanced.

The Rh Factor in Haemolytic Anaemia of the Newborn

Boorman, Dodd, and Mollison (*Journal*, 1942, **2**, 569) suggest that only group O Rh-negative blood should be used for transfusion in cases of haemolytic anaemia of the newborn, with or without severe jaundice. This suggestion is based on the assumption, for which there is already some evidence, that blood of this group will prove to be immune to the action of the immune bodies responsible for the haemolytic process. Unfortunately, at present few laboratories have supplies of potent anti-Rh serum with which to establish a panel of suitable donors. I should like to make an alternative suggestion on the basis of the following two cases.

Case I

A female infant aged 5 weeks was admitted to the Children's Hospital, Birmingham, on Aug. 2, 1939. She was the second child and was delivered at term; the first was said to have been very pale for two months, but was now healthy. Jaundice was observed within a few hours of birth, but was never more than a lemon colour and had faded by the seventh day. Pallor soon became marked and it persisted till admission. On Aug. 2, 4, and 8 transfusions of maternal blood—45, 45, and 50 c.cm. respectively—were given, with substantial improvement in the blood picture and the general condition. A sudden drop in colour index, mean cell volume, and mean diameter was noticed at this time, and the change in shape of the Price-Jones curve was such as only to admit of the conclusion that the infant's cells had been completely replaced by those of the mother. An aregenerative phase ensued from Aug. 5 to Aug. 15, during which no change occurred save for a steady though relatively slow drop in the red cell count. The onset of a fresh reticulocytosis, however, was accompanied by a dramatic change in the Price-Jones curve indicating the steady replacement of the donor's cells by those of the infant. The child died shortly afterwards of a severe intercurrent infection.

Table showing Laboratory Data of Case I

Date	Red Cells (mill.)	Hb %	C.I.	Retics. %	M.C.V.	M.D.	σ
2/8/39	1·23	27	1·08	16·3	92 μ^3	7·92 μ	0·885 μ

Donor's blood, 10/8/39 ..			0·86		68 μ^3	6·92 μ	0·495 μ

Case II

A female infant—fourth pregnancy. First pregnancy: breech delivery, stillbirth. The second child was a full-term female infant who developed a mild form of haemolytic anaemia of the newborn with moderate jaundice. She was treated with liver extract (campolon) only, and is now healthy. The third pregnancy miscarried at 24 weeks.

The mother was delivered at term in the Maternity Hospital, Loveday Street, Birmingham, early on Sept. 2, 1939. The infant's spleen was found to be one fingerbreadth below the costal margin at birth. Jaundice was evident at dawn and rapidly became more pronounced, but it was never severe and faded completely by the fifth day. There was no anaemia at birth, but pallor became progressively more obvious despite frequent injections of campolon. Transfusions of the mother's blood were given on Sept. 10, 12, and 14—45, 50, and 50 c.cm. respectively—with great improvement. Here again the change in colour index, mean cell volume, and Price-Jones curve indicated replacement of the child's cells by the donor's; there was also a short aregenerative phase from Sept. 15 to 20, and thereafter a steady increase in the reticulocyte count, though no significant improvement in the red cell count occurred till Oct. 13. From this date recovery was rapid and uneventful. It is perhaps worth noting that this sudden improvement followed an injection of 1 c.cm. of campolon on Oct. 10. This is the only occasion in my experience of noteworthy improvement following or coinciding with liver therapy in this disease.

Table showing Laboratory Data of Case II

Discussion

These two cases illustrate quite well the point I wish to make. When the degree of anaemia is such that transfusion is urgently needed it may be preferable to use maternal blood, the survival of which for some time is certain, rather than to risk repeated unsuccessful transfusions from a donor selected at random, and therefore probably Rh +, even though rapid destruction of the few native cells remaining may occur. I do not feel that this last is a valid objection to the procedure, for I take it the object of treatment in future will be to circumvent the haemolytic process in the early days by replacing the child's cells so far as possible by Rh-negative cells. On the other hand one would not willingly inject large doses of antibody if it could be avoided. There are two ways out of this dilemma. In the first place it is to be hoped that the serum of every woman whose child is affected will be examined for anti-Rh agglutinins. Where these are present in sufficient strength it will be possible, perhaps, to find a donor whose cells are compatible both with the serum of the child and with that of the mother, and in any case these women should be regarded as unsuitable as donors. The alternative, where facilities are available, would be to use the washed cells of the mother suspended in fresh plasma or saline (a suggestion I owe to my colleague Dr. H. S. Baar).

It may be argued that it is undesirable to depress bone-marrow function so far as in the cases described. I do not believe this effect to be due to the extra dose of antibody, but attribute it rather to success in raising the blood count substantially above the pre-transfusion level. Aplasia and hypoplasia of the bone marrow are exceedingly rare in icterus gravis and haemolytic anaemia of the newborn, which suggests that the main action of the antibody is exerted on the circulating erythrocytes rather than on the erythron as a whole.

Reviews

IMMUNOLOGY

Immunology. By N. P. Sherwood, Ph.D., M.D., F.A.C.P. Second edition. (Pp. 639. 33s.) London: Henry Kimpton.

There are so few modern textbooks on immunity that the publication of a second edition of Sherwood's *Immunology* should be an important event. A good deal of very recent work is in fact quoted, and several new chapters have been introduced, while others have been rearranged and revised. That the book is nevertheless disappointing is due to several factors. A work on this subject should presuppose a sound knowledge of medicine, yet oddly naïve statements occur which on this supposition are superfluous: "Below the ileocecal valve is a lymphoid vestigial organ, the vermiform appendix"; "It is obviously quite serious for the genito-urinary system, heart, central nervous system or lungs to be impaired by acute infections." There is a lack of logical arrangement, seen at its worst in Chapter XV, which, although entitled "Toxins and Antitoxins," deals with, among other subjects, the treatment of pneumonia, sulphonamide chemotherapy, and cerebrospinal fever. In discussing immunization against infections by *Streptococcus pyogenes* the difficulties imposed by the antigenic heterogeneity of this organism are not mentioned. Griffith's work on streptococcus types is mentioned on p. 365, but misdescribed and grossly underrated, and no references to his papers are given. Other omissions and misstatements are fairly numerous, and modern work is sometimes presented in an incoherent form, with too little effort to adjudicate upon it. The author is more successful in tracing the historical development of each aspect of his subject and in laying down well-established principles, and good accounts are given of serological methods, particularly those used in the diagnosis of syphilis.

PSYCHOLOGICAL EFFECTS OF WAR

Psychological Effects of War on Citizen and Soldier. By R. D. Gillespie, M.D. (Pp. 251. 12s.) London: Chapman and Hall. 1942.

One of the few pleasant surprises of the war has been the failure of the predicted epidemic of psychoneuroses to materialize. Dr. R. D. Gillespie's *Psychological Effects of War on Citizen and Soldier* is a valuable and important inquiry on that subject. His opening chapter, on changing concepts in psychoneuroses, is entertaining and rather reminiscent of the first act of *The Doctor's Dilemma*: it emphasizes the willingness of the patient to adopt the doctor's theories, and reminds us that in psychotherapy the relative position of observer and observed is of as much importance as in Einsteinian physics. He goes on to discuss constitutional factors in psychoneuroses, and adds his authority to those who have been forced to adopt the concept of the psychopathic personality. As Osler said, there are some people who will never be able to stand up by themselves. In this respect the earlier psychotherapists were too optimistic. His figures support the view that in the sufferers from war neuroses the trouble started very early in life. That the "broken home" is an important factor is true, but scarcely less important is the inheritance by the patient of genes which contributed to the break. The earliest cultural factor, the family, he concludes, is of great significance in the genesis of psychoneuroses; he discusses both the economic and the constitutional factors, but regards them of much less importance. We like his substitution of "histrionic" for "hysterical": as he says, the hysteric's emotional displays are compensatory for a lack of feeling.

Further consideration of social factors leads him to say: "I suspect that the main preventive of neuroses in doctors and in professional men generally might be summed up in the phrase 'professional attitude.' The individual identifies himself with his job, which becomes a pivotal value for him." In another sphere—namely, shelter life—the appreciation of gregariousness has proved an asset, finding its expression in "We would rather be bombed than bored."

The mediaeval Church condemned *accidie*—i.e., apathy and lethargy—as a deadly sin. For Dr. Gillespie it is a significant symptom in many cases, preceding psychoneuroses on the one hand or antisocial acts on the other; for the skilled and semi-skilled their work is a stabilizing factor, hence the special dangers of unemployment. Unlike some earlier writers the author does not much believe in nervous exhaustion, as if the nervous system were a storage battery which could run down. Genuine exhaustion syndromes, such as were seen after Dunkirk, are rare, and may simulate Parkinsonism.

His opinion that the more slavishly subjected to the will of the State the individual has been the greater the liability to panic or apathy was interestingly confirmed by a German refugee who contrasted the strong inner discipline of the British people with the German, on whom discipline was imposed by authority from without.

It is curious, as he says, that it should have needed a war to bring realization of the truth of old time-worn ideas. The desire of the R.A.F. for anonymity within a community to which one belongs and to which one owes something recalls the attitude of the mediaeval craftsmen. Psychopathology, social science, religious and moral philosophy, agree in asserting that the harmony of human relationships is the highest good. In the thoughts of our younger generation we can discern possibilities for a future civilization. "The common people of England, in their patient endurance, their tolerance, and their sense of fair play, and their readiness to forgive and forget, are such an embodiment as there is anywhere of a national will to that goal." Thus ends a wonderfully heartening book.

THE YEAR BOOK OF EYE, EAR, NOSE AND THROAT, 1942

The 1942 Year Book of the Eye, Ear, Nose and Throat. The Eye: Louis Bothman, M.D. The Ear, Nose and Throat: Samuel J. Crowe, M.D With the collaboration of Elmer W. Hagens, M D. (Pp. 640; illustrated 18s) Chicago: The Year Book Publishers, Inc; London: H. K. Lewis and Co.

The 1942 Year Book of the Eye, Ear, Nose and Throat has reappeared with its customary regularity and with undiminished excellence. It remains in the hands of the same pair of editors, Dr. Bothman of Chicago for the eye, and Dr. Crowe of Johns Hopkins of the ear, nose, and throat. The general arrangement is the same as usual, and at the beginning there is a special article by Dr. Bothman on avitaminosis in ophthalmology. There is no special article by Dr. Crowe, but the editorial comments at the end of many of the abstracts form much of the best reading, and no illusions are allowed to remain to a writer whose opinions or conclusions are not considered to be well founded. A good example of this is the comment on the article on oestrogenic implants in treatment of atrophic rhinitis. The importance of the ear in flying, a subject which received special attention in the Year Book for 1941, is not neglected, and the editor has revived two articles by Dr. Arnold Rich on the physiology of the Eustachian tube and its related muscles, and on the innervation of the palatal muscles, dating back to 1920. Modern developments in flying lend a renewed interest to these, and it is probably not generally known that Dr. Rich showed that the sole influence in causing the Eustachian tube to open is the contraction of the tensor palati muscle. A word of appreciation is due to the precision, brevity, and clarity with which the abstractors have performed their task. The Year Book for 1942 is well up to the established standard, though it is inevitable that some of the articles abstracted should be of a repetitive character.

Notes on Books

In producing the eleventh edition of his excellent *Text-Book of Midwifery* Prof. R. W. JOHNSTONE has thoroughly revised the whole volume. A new chapter dealing with radiology in obstetrics has been added and those sections concerned with hyperemesis gravidarum, disproportion, abnormal uterine action, and menstrual pathology have been largely rewritten. The result is a considerable improvement in a book which was previously good. It is published at 25s. by A. and C. Black.

The thirty-seventh edition, for 1942-3, of the *Girls' School Year Book* has been issued by Messrs. H. F. W. Deane and Sons, 31, Museum Street, W.C.1, at 7s. 6d. This is the official book of reference of the Association of Head Mistresses, and, in addition to the usual authoritative information, it gives, so far as is possible, the details of many moves of schools necessitated by the war.

SURGEONS AND SURGERY IN LENINGRAD*

BY

Prof. N. BLINOFF

Leningrad Postgraduate Institute and Blood Transfusion Institute

Leningrad has been besieged for over a year now. The absence of a normal influx of food products (at one time its complete cessation) and the severe bombardment have had their effect on the life of the town and in particular on the work of the surgeons.

The beginning of the siege was heralded by violent air raids and frequent bombardments, as the result of which there were a large number of wounded among the civilian population. It became necessary to open new surgical wards in already existing hospitals and even to create new hospitals. The civilian hospitals were all transformed into military ones and also served as evacuation hospitals. The wounded were admitted straight from the battle front, after first-aid treatment only. The ordinary surgical work of the town had to be done in addition to this.

The deficiency of food and the use of "food substitutes" have changed the type of patients admitted to the hospitals. There were very few patients with acute appendicitis, but the number of cases with perforated gastric ulcer increased more than tenfold as compared with peacetime, and there were very many with strangulated hernia and obstruction. There was an especially large number of cases with coprostasis on account of the faulty and rough food.

Planned surgical operations were not performed; only emergencies were done. The usual principles of treatment of gunshot wounds were observed: excision of the edges of the wound, etc.; the wounds were not sutured. In some clinics a sulphonamide was applied locally. Fractures from gunshot wounds were, as a rule, treated by plaster dressings; extension was seldom applied as the wounded had to be moved from one hospital to another. The method of closed plasters left on for a long period was used widely. In the treatment of shock, blood transfusions, blood replacements, and anti-shock solutions were extensively employed. There was no shortage of blood or of solutions. The Blood Transfusion Institute began scientific and practical work on the method and technique of preparation of different blood-replacing solutions. Some surgeons made a habit of using sphagnum moss for surgical dressings.

As surgeons had for the most part been mobilized, there were not many left to serve the civilian population. Short two-week courses were organized by the Postgraduate Institute and new cadres of surgeons were formed. Several hundred doctors received postgraduate training in that way. Two scientific conferences were held in October and November, 1941, to discuss methods and results: 500 doctors attended and 17 addresses were delivered on a variety of subjects.

Then severe cold weather set in; on account of extensive damage the electricity supply failed in most of the buildings, so work had to be done with the aid of oil-lamps or night-lights. Then the water supply gave out. There was very little coal for central heating and practically no wood, so the temperature of the wards, operating theatres, and dressing stations was very often at freezing-point. Temporary stoves were installed, and by using fences and wooden huts as logs the staffs of the hospitals were able to raise the temperature several degrees above freezing-point. The doctors made their rounds in fur overcoats covered by white gowns, and dressings had to be performed in the wards. The wounded often had to lie in bed fully dressed. The author of this article frequently had to do blood transfusions in a fur coat and a fur hat and keep his hands warm by putting them in warm water. Only in the older hospitals could some of the work be performed in the operating theatres. Later the number of surgical cases diminished abruptly and surgical beds could be filled by medical cases.

The severe cutting down of rations and the intensely cold weather produced a peculiar disease—an alimentary emaciation, which appeared in different forms (oedematous and dry) with a variety of surgical complications such as gangrene of fingers, trophic ulcers, etc. This was followed by avitaminosis. With the advent of the spring surgeons began to get active again. In April, 1942, the first surgical conference of the year was held: 150 civilian and military surgeons were present. After that regular meetings were held every third Sunday. There were several scientific conferences on blood transfusions, trauma, etc. It showed that surgeons were active even during the worst part of the blockade. Most of the debates and meetings were on treatment of different types of wounds, but some of them dealt with other subjects, such as conservation of blood, preparation of dry plasma, and transfusion of sterile homo- and hetero-sera. One meeting was devoted to the question of alimentary emaciation and its treatment by transfusion of blood, plasma, and blood-replacing solutions, and also by the use of blood preparations (ferro-haematogen compound). The biochemical laboratory of the Institute gave a detailed account of the biochemical changes in the blood of emaciated patients. Altogether 22 lectures were given. Two conferences were held at the Traumatological Institute. At the conference held in September, 1942, and organized by the town council's health department 400 surgeons attended. Samarin gave a lecture illustrated by 200 cases on the marked action of sulphonamides on the healing of gunshot wounds. Blinoff dealt with the classification of complications after blood transfusion. Kasakevitch and Nadein summarized their experience of 1,000 cases of gunshot fractures treated by the application of closed plasters. Epstein reported on contractures due to scurvy. A special meeting was devoted to wounds of the chest. In spite of heavy gunfire and bursting bombs during the sittings the hall was full all the time. A conference of nurses also roused great interest. No surgical journals appear in Leningrad now, but surgical literature is printed in pamphlet form.

The experience of Leningrad has shown the great variety of responsibilities of surgeons in civilian hospitals. In spite of the very reduced number of surgeons the whole population was efficiently looked after, as everybody worked with redoubled energy. The second winter in the besieged city does not cause any anxiety to the surgeons of Leningrad. The atrocious conditions of work during the last winter will not recur. The hospitals are now adapted for winter work; they have enough wood for heating purposes, there is a better assortment of drugs and dressing materials. The surgeons will be able to give their help to the population remaining in Leningrad more confidently, because they know that the Red Army will not allow the enemy to enter the town. The Soviet Union is proud of the defenders of Leningrad.

VENEREAL DISEASES

Distribution and expansion of treatment facilities, the value of educational work, and the special measures to be taken under Regulation 33B are the subject of the Ministry of Health's latest circular (No. 2727) on venereal diseases. In the first place, the circular states that a local authority should aim at a distribution which provides that no part of its area is more than 10 miles from some treatment facilities, though in present circumstances a treatment centre within this distance may not always be practicable. The services of general practitioners should, therefore, be used as set out in Circular 2226 (*Supplement*, Jan. 4, 1941, p. 2), which provides for the employment of suitably qualified G.P.s who would give treatment at their own surgeries and undertake any necessary training. Secondly, local authorities are urged to make full use of the literature, posters, etc., prepared by the Central Council for Health Education. The council will advise authorities on ways of expanding their own educational arrangements, supply films and literature, and suggest lecturers. In addition, each authority should publish locally regular information about treatment centres and arrange for publication of articles on venereal diseases and their treatment. Finally, the circular refers to the powers conferred on special practitioners and medical officers of health under Regulation 33B (*Journal*, Nov. 21, pp. 611, 616). A memorandum on the Regulation by Sir Wilson Jameson with some notes for the guidance of special practitioners and copies of the Rules and forms are enclosed with the circular, which has been sent to local and port health authorities and their medical officers of health.

* Cable received by the Anglo-Soviet Medical Council.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY JANUARY 30 1943

A MEMBER RESIGNS

During the 110 years of its existence the B.M.A. has not been without its critics, and at times the tide of criticism has risen high. Much of this has been unjust and founded on ignorance of what the Association has in actual fact done and of what it intends to do in terms of its declared policy. No organization that does not remain static can avoid making some mistakes in attempting to achieve what it conceives to be its true aims: it is here that the help of the constructive critic is welcome. At a time like the present, when so much is in flux, when so much is being challenged, discontents tend to come to the surface, and in some, but rare, instances so acutely that a doctor may resign his membership of the B.M.A. by way of protest. As it is possible that the expressed grounds for dissatisfaction may be held by others, we feel it may clear the air to publish a recent letter of resignation, and to examine its contents critically in the interests of both the writer and other members who may in part share his views. The letter reads as follows:

> "I wish to resign my membership of the Association for the following reasons:
>
> "1. The Association is not representative of the profession and particularly of the younger members. The British Medical Association has made no effort to ensure that members of the profession in the Forces shall have a major say in planning the medical services of the future. In short, the medical officers of the future will have to practise their profession according to the plans of a previous generation, in whom they have little or no confidence.
>
> "2. The British Medical Association, on account of their inability to inspire confidence in the minds of the younger members of the profession, have split the profession into various other groups of medical thought. This is likely to retard rather than advance medical progress and destroy its necessary precursor, the confidence and support of the general public.
>
> "I assume that you will not wish to publish this letter in view of your policy to publish only 'soft letters' which do not conflict with high British Medical Association policy, but should you decide to do so I have no objection."

Let us take his first point—that "the Association is not representative of the profession and particularly of the younger members." It is difficult to see how the Association could be representative of anything but itself, being—as it is—a voluntary organization of medical men. Surely the Association is what its members make it, no more and no less. The men who "built" the B.M.A. constructed a machinery for giving effective expression to the wishes of its members. No policy can become the declared policy of the B.M.A. unless it is accepted by the Annual Representative Meeting—that is, by the representatives elected by the members of the B.M.A. If the members of the Association do not attend their divisional meetings in sufficient numbers, and do not see that their views are put before the A.R.M. through their elected representatives, then who is to blame?

The second point made by our correspondent is that "the British Medical Association has made no effort to ensure that members of the profession in the Forces shall have a major say in planning the medical services of the future. In short, the medical officers of the future will have to practise their profession according to the plans of the previous generation, in whom they have little or no confidence." This is not true. Since the Medical Planning Commission was set up the Association has been very fully aware of the great disadvantage of not having the active participation of men in the Forces in drafting blueprints for the future. And the awareness of this disadvantage has been fully shared by the other bodies appointing to the Commission—the English Royal Colleges, the Royal Scottish Corporations, the Society of Medical Officers of Health, the Faculty of Radiologists, the Medical Women's Federation, and the Parliamentary Medical Committee. So far as the B.M.A. is concerned, it has made constant efforts to obtain the views of serving doctors on the future of medicine, and to this end has successfully urged study groups to invite the attendance at their meetings of serving doctors from neighbouring units. When the matter was debated at the Annual Representative Meeting in September, 1942, the Secretary of the Association recounted how a group of R.A.M.C. men had complained to him that their C.O. had forbidden them to transmit the substance of their discussions on medical planning, and how he had at once successfully taken this matter up with the Director-General of Army Medical Services, asking him to instruct Commands to allow such meetings and the transmission to the B.M.A. of the findings of such meetings. It should nevertheless be borne in mind that not all the younger members of the profession are serving with the Forces, and that those who are do not constitute the majority of the profession. May a centenarian modestly suggest that it is somewhat arrogant for men just beginning to learn the difficulties of their profession to assert that the future is their own special province and that men with experience of the past are thereby incapable of having any ideas on what is to come.

The third criticism is this: "The B.M.A., on account of their inability to inspire confidence in the minds of the younger members of the profession, have split the profession into various other groups of medical thought." Is it not largely the case that some members of the profession take very little interest in the work of the Association to which they belong until something goes wrong which affects them personally? And is it not true that when this happens they look round for a scapegoat—which is conveniently present in the form of "The B.M.A."? The apparent apathy of younger B.M.A. members arises in normal times from many factors which are social and general rather than professional. When a young man qualifies, medicine is for him a matter almost entirely of healing the sick and preventing illness, and when he begins to practise he is preoccupied with matters affecting his career, with the business of earning a living for himself and perhaps for a family. As his responsibilities grow he gradually becomes more aware of himself as one of a group of men earning a living in a certain way, and of the possibilities of altering terms and conditions of work to the advantage of himself and of his patients. And on top of all this some years must elapse before he finds himself with enough leisure to devote to such problems. This state of affairs is not peculiar to the medical profession but is characteristic of modern society. We believe that this state of affairs is unsound and that all men—and perhaps especially young men—should have leisure in which to reflect upon the kind of professional life they are leading and upon the professional ideas and ideals they hold. But why blame the B.M.A.? And why accuse it of having "split the profession into various other groups of medical thought"? It is self-contradictory to assert that the B.M.A. can formulate views which are not held by its members, because it is the members—and once more reiteration of the fact seems imperative—who do the formulating.

It may be, however, that the feeling behind the criticism is one of dissatisfaction with the conflicting aims of groups of the profession formed for various reasons but certainly not because of any malign activity of the B.M.A. There are differences within the profession, and most unfortunately these are not always based upon intellectual or idealistic conceptions of what the aims of medicine are or should be, but upon a selfish and narrow view of the interests of the particular group to which this or that man belongs. If there is one policy that has been characteristic throughout the whole history of the B.M.A., it is the policy of uniting medical men, whether in their professional interests or in the interests of the health of the people among whom they live. Without labouring the point any further, we would like to quote from an article by Prof. R. S. Aitken in our contemporary[1]: "If we had an integrated medical profession, loyal and pulling together, we could exert an undreamed-of influence for good in politics and economics. . . . 'Idealism!' you say mockingly. 'You will never get doctors to work together like that.' Why not try?" We can only echo his question.

The last sentence of the letter printed above we reproduce with reluctance because of its absurdity. But, absurd though it appears to us, the view has been expressed before, and so it should see the light of day and be finally disposed of. We should have thought, for example, that the publication in this journal of the correspondence condemning the setting up by the B.M.A. of a Planning Commission would once and for all have laid low this odd legend of the crafty censor. Obviously no editor of a journal can be a passive retailer of other men's views, and obviously he must select and reject matter for publication, if for no other reason than that printing space has its limits. If any bias is shown, it is in the direction of giving more space than some would think justifiable to "the other point of view," especially when it is at times intemperately expressed. If anyone doubts the fact of this policy, he should turn to the first three letters on the pasteurization of milk which appeared in the *Journal* of Jan. 9.

Whatever may be the turn of medical events in the near future, the direction they take will be determined in no small measure by the fact of unity or disunity of the doctors of this country. Strong individualism has always been characteristic of British Medicine. If the profession is to be able to resist the imposition on it of a medical service out of harmony with medical ideals, then sectional interests must yield before the common aims all doctors share, and before the common decision on how these aims are to be reached. And the common ground must be sought if the medical profession is to offer the public a service which will make available to every man, woman, and child in the country the complete benefits of medicine in the prevention and cure of disease and in the promotion of health; and if the fundamental ideals of medicine are to be respected and preserved by Government. Such a unity cannot be reached without some sacrifice of personal, sectional, and institutional interests. Are the doctors of this country prepared to do this? The testing time may not be far off.

HOUSES TO LIVE IN

Those who were brought up in stuffy Victorian houses, large or small, must sometimes wonder how they ever escaped alive. Francis Bacon said that houses were built to live in, not to look at; but many houses of the last century fulfilled neither requirement. The builders paid scant attention to health or aesthetics or even domestic convenience. The neglect of natural lighting and ventilation, and of dryness and warmth, the primitive sanitary arrangements, the likelihood of vermin infestation, the lack of provision for food storage, the unventilated passages, the dark staircases, the basement living rooms must all have had their reflection in the heavier mortality and morbidity rates of the generations which inhabited them. The modern house is better—decidedly better—but it is not as well planned as it might be. And its planning in relation to other houses—as in ribbon development—almost makes the observer doubt whether this country really has a right to be called civilized. At the request of the Central Housing Advisory Committee of the Ministry of Health, the Royal College of Physicians, through its Committee on Social and Preventive Medicine, has drawn up a memorandum on "Design of Dwelling Houses," having in mind the small house, and principally, though not exclusively, the house built under a local authority housing scheme.

Health considerations enter even into the disposition of rooms in a house in relation to one another. The parlour or "best room" in the small house has no longer the mortuary air which it once had, but this memorandum proposes its abandonment altogether. It is a room only used on special occasions, difficult to keep warm, and apt to become damp and unwholesome. It would be better to add to the size of the living room than to have two smaller rooms one of which is rarely used. Another house convention is the "second" bedroom, presumably where the children sleep. The College, intent on scotching the foolish and unhealthy doctrine that children require less air space than adults, urges that the second should be at least as large as the principal bedroom occupied by the parents. Three bedrooms are regarded as the minimum for families of between two and five persons. Another suggestion is that the local authority should reject any plan for a new house unless it includes a bath with proper arrangements for a piped supply of hot and cold water. It is thought advantageous to place the bath and the water-closet in the same room, for the water-closet is then more likely to be kept in a wholesome condition, and also people are thereby encouraged to wash their hands after using the toilet. The combined bathroom and water-closet should be kept apart from, and not communicate directly with, any public room or bedroom. The kitchen-scullery should be the housewife's workshop, fitted solely for her convenience, and not used as a second living room. The food store, something better than a mere cupboard, should have a northerly aspect, and its external opening should be protected by wire gauze. Perhaps after the war there will be refrigerators for all. Something will have to be done about the dustbin, which is a possible source of contamination as well as an unsightly tail-end to the domestic procession. In block dwellings the "shute" system with movable container is preferable. The College does not come down wholly against the coal fire. It considers it desirable, partly on psychological grounds, that there should be at least one open fireplace burning coal or smokeless fuel.

Up to now houses have generally been constructed for occupation by the married couple with a family, and any differentiation has been on economic grounds. It is useful that housing authorities and private builders should be reminded that houses need to be adapted to the social condition of the prospective tenant as distinct from his purse. There is, for example, the question of houses for the old, which is becoming more important with an ageing population. It is calculated that by 1950 about one person in eight will be over 65. Many old people, of course, are able to live comfortably with relatives; some have to be transferred, on account of infirmity, to institutions; but many require houses, and the College suggests that every housing scheme should include a number of houses suitable for old persons. These would not be of the almshouse type but possibly bungalows, in the construction of which the lessened agility of the old, their liability to accident, and their simpler needs would be kept in mind. When stress is laid, as it is in this memorandum, on the helplessness of old people and the difficulty they have in maintaining personal and domestic cleanliness it is forgotten that the septuagenarian of to-day is a much more lively person than his frequently bedridden predecessor of fifty years ago. He has lived through a generation of health instruction in one form or another; the force of a healthier habit will not be easily broken even by increasing infirmity; moreover, the complaints which attend old age seem now to be less disabling. Nevertheless, it is a good thing that there should be some special houses for the old.

---

[1] *Lancet*, 1942, 2, 235.

Similar considerations apply to the housing of the tuberculous and the crippled. The College believes it to be a sound principle not to segregate the tuberculous in colonies, but to have them in the general community, in houses in which at any rate one bedroom is favourably situated as regards access of sunlight and fresh air, and has special windows opening more widely than the usual pattern. There is also the question of the mentally defective, the dirty, and the anti-social. The suggestion is made that certain houses of a rather bleak kind should be designed for the worst type of undesirable tenant, that these houses should include such features as concrete floors, impermeable walls, and, so far as may be, indestructible fittings, and that they should be open to rigid inspection by competent officers of the local authority. Such a system has been carried out in Holland, where these tenants on good behaviour are permitted to "graduate" to houses of a better type.

Flats will continue to be the choice or the necessity of large numbers of people. The College favours a three-story house consisting of a two-story tenement for a family and a single-story flat on the top floor for childless persons. But whatever the type of dwelling, just as no man liveth to himself, so no house is built to itself. The sense of incompleteness which clings about many new housing estates is the lack of community basis. Town and country planning hardly comes within the scope of this memorandum, but it does urge that all housing estates should be grouped around certain centres of public service, education, and recreation. Among these is mentioned a health centre, not in the wider sense in which that term has been used in recent discussions, but the assembly under one roof of all the services of preventive medicine. In this memorandum—which is not the first of its kind which the College has issued: there was a very useful one in 1936 on domestic heating by gas—an important contribution has been made to a major problem, and we hope that its counsels will be duly considered in the rehousing to which the Government intends to give high priority after the war. For the College to give a lead in this important matter of housing in relation to individual health and social welfare is an encouraging sign of the times.

STATISTICS OF VENEREAL DISEASE

During recent discussions on venereal disease various widely differing estimates of the number of patients defaulting during treatment have been made. That such large differences can arise emphasizes the paucity of data on what is an important social and health problem. The deaths resulting from venereal disease are classified and tabulated in the Registrar-General's Statistical Review, but national statistics relating to the incidence of venereal disease are scanty. The number of cases dealt with at treatment centres in England is given in the annual report of the Ministry of Health. The number of cases dealt with for the first time at centres in England and Wales is stated in the annual report of the Chief Medical Officer in slightly greater detail, and totals are given which include and exclude cases transferred from centre to centre and those returned with the same infection after being struck off the books in previous years. These form a considerable number: in 1938 the total number of cases by the first method was 60,800 and by the second 49,415. The deductions that can be made from the statistics published in these reports are that the number of cases of syphilis had been steadily declining in recent years, whilst the number of cases of gonorrhoea fluctuated around a fairly constant level; the ratio of male to female cases was 3 : 2 for syphilis and almost 4 : 1 for gonorrhoea. No further information is published for the country as a whole, although apparently it was available, because in 1936 the Minister of Health was reported[1] as stating: "So far as discharge and tests of cure after treatment were concerned there was an improvement, for in 1925 the percentage was 12.9, whilst in 1935 the figure had risen to 17.5." No indication of the fate of the remaining 82.5% was given. Various speculations on the history of these patients can be made; the easiest guess is that they were not cured and were either incurable or defaulters, but such a conclusion seems too obvious to be true.

Although no information is available from national figures, the reports of the medical officers of local authorities indicate the approximate position. These reports, in which the administrative aspect is naturally important, tabulate the statistics in varying ways and detail. The numbers of cases discharged after completion of treatment and final tests of cure during 1938, which was the last year for which detailed reports are readily available, in the cities of Liverpool, Manchester, Birmingham, and Glasgow were 17.4, 19.2, 21.2, and 20.2% respectively of the total cases treated during the year. The percentages of defaulters were 18.8, 23.5, 15.7, and 26.4. The defaulters can be divided into two classes: (1) those who ceased to attend before completion of treatment (known to be in an infectious condition and responsible for the spread of much disease); and (2) those who ceased to attend after completion of treatment but before final tests of cure. In the former 15.5, 16.2, 10.7, and 16.0% of the total cases defaulted; and in the latter, 3.3, 7.3, 5.0, and 10.4%. Those transferred to other centres amounted to 19.5, 6.9, 8.5, and 12.7%, and those remaining under treatment at the end of the year were 44.3, 50.4, 54.7, and 40.7% of the total cases. If these local figures can be taken as giving a broad picture of the conditions within the country we should expect, for the whole country, the percentage transferred to other treatment centres to be much lower, as only those transferred to private practitioners would appear in this group. The percentage of defaulters might be higher, because in the local returns the transferred cases appear in the denominator. These cases are, in the four cities, more numerous than the entrants by transfer, and it would not be safe to make the assumption that there were no defaulters among transferred patients.

---

[1] *Hlth. Emp.*, Sept., 1936, 11, 231.

If adequate national statistics had been made available confusion as to the percentage of defaulters would not have arisen. It is possible that with a percentage of 17.5 patients who completed treatment and tests of cure the defaulter rate was in the neighbourhood of 25–30%, and almost three-quarters of those who defaulted were known to be still in an infectious condition. About half the patients were probably still under treatment at the end of the year.

OPERATION FOR THE ORCHITIS OF MUMPS

The orchitis caused by the virus of mumps may be as acute as the epididymo-orchitis caused by the gonococcus. Within a few hours the testis swells to three or four times its normal size and becomes so acutely sensitive that the patient cannot bear to have it touched. The infection is often associated with a high temperature and sometimes even with delirium. What is still more important is that the acute infection is followed in 54.7% of cases by testicular atrophy due to cell necrosis brought about by the great rise in intratesticular pressure. In 1864 Henry Smith advocated that an acute epididymitis due to gonorrhoea should be treated by multiple puncture of the tunica albuginea. A. Wesselhoeft and S. N. Vose[1] recommend that the same method should be applied to the severe orchitis in mumps. It would indeed seem that relief of the increased intratesticular pressure is more necessary in the case of mumps than in that of gonorrhoea, because the risk of subsequent atrophy in the former case is far greater. The writers emphasize the necessity for intervention before the inflammatory process has reached its peak. In the 9 cases in which they operated sufficiently early the testicle recovered without undergoing subsequent atrophy. In the one instance in which incision was postponed some degree of atrophy followed. For multiple punctures they substitute complete exposure of the swollen organ and a longitudinal, or sometimes a crucial, incision of the tunica albuginea. The operation not only affords an immediate relief of pain but also brings about a rapid fall in the temperature. It is only necessary in the fulminating type of case, which constituted 10 out of the total of 24 cases reported upon. Atrophy is only likely to follow the very acute infections, and the less severe cases need not be subjected to operation.

DIAGNOSIS OF PERIPHERAL NERVE INJURIES

In all medical and surgical practice good treatment is based upon careful investigation and accurate diagnosis. In this war many special problems come to the less experienced in unusual numbers. Among such problems, requiring the most careful investigation in early treatment, are injuries to peripheral nerves, and for this reason alone the valuable pamphlet[2] issued by the Nerve Injuries Committee of the M.R.C. is to be warmly welcomed. This excellently illustrated atlas should prove of great help. It comprises mainly a series of excellent photographs which demonstrate one method of testing the action of every important muscle of each limb. The nerves are taken separately, and the muscles supplied are shown in the order of the origin of their branches from the parent trunk, an arrangement which will be of use in determining the level of the lesion. In the legends the spinal segments chiefly responsible are indicated, and thus further help is given in the elucidation of radicular injuries. Sensory distributions and their variations are represented in line drawings of typical lesions at different levels. With the atlas itself there is little to criticize, it is so good. Among minor points that might be improved is the differentiation of the action of abductor pollicis longus from that of the abductor brevis. It would perhaps have been better if it could have been made clear that during the test for quadriceps action the heel is completely raised off the examination table. The illustrations Nos. 47 and 48 dealing with the action of the tibialis anterior and extensor digitorum longus have been misplaced. The legend 47 refers to 48, and vice versa. The introduction, however, is open to serious criticism, especially because the pamphlet is intended for the inexperienced. There is much obscurity, and even inaccuracy, in the statement concerning the action of a muscle as prime mover, fixator, synergist, and antagonist. The use of the flexor carpi ulnaris as an example is unfortunate. Its action as a prime mover is to flex and adduct the wrist. In the movement of flexion of the wrist it acts as a synergist with flexor carpi radialis. The flexor carpi ulnaris is an *antagonist* (with radialis) "when the wrist is actively extended," and a *synergist* "when the fingers, but not the wrist, are extended." The booklet describes these actions the other way round, and so the inexperienced reader will be led astray. The valuable system of recording the strength of muscular action used by most orthopaedic surgeons for charting paralysis in anterior poliomyelitis is mentioned, but it is a pity that the method of carrying out the test for each of the five gradings mentioned was not described for a representative muscle group. There is paper left bare in the pamphlet, and without such description the reference to the system is not very helpful.

DR. BOYD'S GIFT TO MANCHESTER

The late Dr. Robert Boyd, formerly Chairman of the Manchester Division of the Association, concerning whom an obituary notice appeared in our issue of January 23, made a most generous bequest to the Association for the benefit of his professional colleagues in the Manchester area. The gross value of Dr. Boyd's estate is in the region of £100,000. Subject to certain life interests, the residue of the estate is left to the British Medical Association "to be applied as to as well the capital as the income thereof for the purpose of endowing or contributing to the endowment of a British Medical Association House in the district of Manchester for the benefit and use of all qualified and registered doctors practising in Manchester and the surrounding districts, the power of making regulations for the conduct and use and the powers of managing and administering the said House to be vested in the Governing Committee or Body for the time being of the Manchester Division of the British Medical Association."

"B.M.A. House, Manchester," will be a fitting memorial to Dr. Boyd in his own city. His great gift will, we hope, serve as an inspiration to others, singly or collectively, to establish "B.M.A. Houses" in the principal regions of the country, so that each large grouping at the periphery may have a local habitation and a name.

The Central Council for Health Education has arranged for a whole-day conference on Friday, Feb 26, on "Health Education and the Venereal Diseases." The morning session, from 11 a.m. to 1 p.m., will be devoted to the general problem and will be opened by the Minister of Health; he will be followed by the Archbishop of Canterbury, President of the C.C.H.E. Afternoon speakers will include Lord Winster, Dr. Thomas Garland, and Dr. Hamilton Wilkie

[2] M.R.C. War Memorandum No. 7. H.M.S.O., 1942, (2s

ASPECTS OF WAR MEDICINE IN THE R.A.F.

BY

D. STAFFORD-CLARK, M.B., B.S.
Squadron Leader, R.A.F.V.R.

The first duty of the Service medical officer in war is to maintain the effective strength of his unit by every means in his power. This duty precedes his individual obligations to his patients even as those obligations precede his personal gain; moreover, it charges the medical officer of the Royal Air Force with a threefold responsibility. He must be a sound, responsible, and decisive clinician in both medicine and surgery; he must show an imaginative appreciation of the physiology and psychology of flying; and he must always concern himself not only with the physical welfare of his men but above all with their morale. Failure to recognize this underlies the fallacy that much of a junior M.O.'s work is exasperatingly trivial, whereas an intelligent grasp of this aspect of war medicine enables him to render unique and invaluable service.

Sick Parade

The morning sick parade is one example. On the average station of the Royal Air Force not more than 15 men and 3 or 4 women are likely to report sick on any normal morning. Yet even of that handful several may appear and reappear with melancholy and improbable tales of woe. The daily sick list admits of an immediate division: one section being a minute proportion, constantly changing, of the vast healthy majority who happen to have something wrong; the other a large and more consistent selection from the minority of feeble spirits and faint-hearts—some martyrs to a consuming self-pity, some hopeful scroungers, some simply malingerers, all essentially indifferent to the challenge of this war and unable to accept its reality. Their symptoms, as an escape from disagreeable duties, concern them far more than the purpose of those duties or the need for their performance. Even as neuropaths they are clinically insignificant—trivial in everything but the waste of man-power they represent and the sick-hearted spirit they display. Yet unless the M.O. succeeds with them their numbers may increase until the sick parade itself swells and the efficiency of the station begins to decline. Here the M.O.'s function is mainly interpretative. From the resources of his own conviction he can give them insight not only into the shallow inadequacy of their symptoms but also into the nature of their obligations. Simply, vividly, in a few words he can make them see that sick quarters exist to give help and encouragement but not sanctuary, to maintain or restore fitness rather than to excuse on grounds of ill-health. The reality of war needs emphasizing to many whose nearest approach to it was the sound of a bomb "in civvy street"; but the explanation must be crisp and vital, its implications focused on the job of each individual. After this "pep-talk" the relations of the patient and the M.O. are on firmer ground, a placebo if indicated becomes a tonic, and resolve may well be rekindled: without it, rebuke, no matter how just, may fail.

It is easy for an unreflective tradesman in the R.A.F. to imagine that he will never be called upon to fight for his life or his unit with his hands or a gun. That is the business of the Army—or the "Ground Defence," as the R.A.F. Regiment was previously called. He feels no thirst for battle; he is a rigger or a flight-mechanic, not a soldier: so runs his mind. So when he is included in the Emergency Reserve or sent on a "backers-up" course he is tempted to react by reporting sick. This is not his trade, not what he joined the R.A.F. to do; if he'd wanted to be a ruddy soldier he could have waited until he was called up for the Army.

At this point the M.O., faced by a querulous patient with his grievance thinly disguised as a vague ache or "terrible pains," has a chance once and for all to prise the scales from those unwilling eyes. Even the most skilled artisan is useless with a bayonet through his belly; and we may all share that fate unless each can help to avert it by his own efforts, as well as practise his specialty. The man who requests a chit excusing him from elementary combatant training may justly be asked to whom he intends to present it: to the German paratrooper who is about to kill him? Does he suppose that the trouble of learning a soldier's job when he already has a trade warrants its evasion, even in his own interests? Might it not perhaps be better to learn all he can about how to fight on the ground? The enemy forces who will attack aerodromes will be the best-trained and best-equipped troops available. When they arrive, will ignorance then be bliss? The airmen who were massacred on the aerodromes at Crete learnt too late the answer to that question.

By this time the trivial ailment occupies a less prominent place in the airman's mind. Such essentially belligerent medicine is an inevitable daily routine with the Service M.O.

The M.O.'s Great Responsibility

But it is in his relations with his air crews that the highest degree of responsibility rests upon the M.O. He must be their friend, their adviser, and sometimes to the younger members of his squadron their elder brother. He must inspire their respect as a man as well as their confidence as a doctor Apart from the preservation of their health, in itself a considerable undertaking, he must ensure that they fully understand the essentials of first aid in the air, the use of oxygen, the effect of pressure changes at altitude on their bodies, and the relevant facts about venereal disease.

To give his advice about first aid in the air a background of experience, to widen his own horizon, and to enter as completely as he can into the realities of their existence, he should take every available opportunity of flying with the crews in the squadron aircraft. If he is keen, willing, and unassuming about this he will not find such opportunities hard to secure. The familiarity that flying by day and night will give him with the problems of space and stowage in twin- or four-engined aircraft, the position and accessibility of first-aid outfits, and the difficulties of movement in full flying kit will sooner or later stand him in good stead: for after a crash with bombs on board, followed by fire—one of the most serious and urgent disasters that confront an M.O.—there is a space of minutes only in which to effect rescues before the bombs explode. The use which can be made of this period depends on the M.O.'s knowledge of the crews' positions in the aircraft and their ways of escape. The respect and confidence that an M.O.'s performance in such crises will command among the flying men in his squadron, coupled with the companionship gained from having had him fly with them, will equip him to fulfil his surpreme obligation—the responsibility that he shares with the squadron and flight commanders for the maintenance of air crews' morale.

This is not the place to discuss the details of that responsibility or the problems of its fulfilment. It is enough here to say that the guidance and instruction so freely proffered to the young M.O. by the R.A.F. Medical Service are positive and intellectually acceptable; once understood, enriched by experience, and applied with courage, imagination, and common sense, they increase substantially his value as a doctor. His task is not easy, nor is it always pleasant. Decision and responsibility rest more heavily and more individually upon him than ever they did in his days as a house-officer. But in the indispensability of this special service lies its merit and its reward.

Another feature of the M.O.'s life is general medical instruction. Apart from his lectures to air crews, he is responsible for the training of his staff in sick quarters and for the guidance of airmen in simple hygiene and first aid. Under present conditions it is not practicable to give all the airmen on a station an extended course of medical lectures. Postings overseas, courses, and the usual changes of station personnel preclude this even if it were desirable. But it should be possible to tell airmen all that they need to know about first aid in one lecture, of which the recognition and treatment of shock are the keystone. Haemorrhage, fractures, burns, penetrating wounds, and unconsciousness can all be introduced and related to the central theme, in diagnosis and treatment. The men will probably then know at least enough to do as little as possible to a gravely injured man without forsaking common sense for rule of thumb. The idea that first aid is a special subject with a literature and academic tradition of its own has always seemed to me to be a dangerous presumption. A course of lectures with apparently detailed and separate instructions for various types of injury may rob men of their precious natural humility in the presence of physical disaster without really equipping them to relieve it. It is not in the patient's interest that the partly trained should feel a surgical confidence.

Training of Medical Orderlies

The training of medical orderlies calls for a different approach. They make up a small but essential section of the station, directly under the command of the M.O. They are recruited largely from completely untrained and inexperienced civilians, and, apart from an initial six-weeks course, are wholly dependent upon the M.O. for their instruction, the interpretation of their duties, and the inspiration to perform them to the utmost of their ability. He in turn is dependent upon their loyalty, efficiency, and enthusiasm for the smooth running of his department and its reliability under all conditions; for he will have no highly trained sisters or nurses to appreciate the immediate medical implications of an emergency or anticipate his needs in a time of stress. His staff will reflect the value of his teaching and his example; it behoves him always to remember that. The very obligation is stimulating: to teach as well as to treat, to explain as well as to diagnose. This involves both lectures and demonstrations. In practice it is a sound plan to include teaching rounds in the ward whenever there are suitable cases, as this not only stimulates interest and accustoms orderlies to observation at the bedside but also gives them a feeling of studentship which they enjoy and which fosters discipline and loyalty to their officer.

He must display leadership and a capacity for organization as well as professional ability, for the grouping and handling of medical resources in men and equipment are also among his responsibilities. Practical schemes for dealing with casualties from land or air attacks, from crashes, or from aircraft returned with wounded on board demand constant practice and revision. Simplicity cannot be too highly prized in such schemes. Under the impact of extreme crisis—for example, collision of two bomber aircraft on a runway while landing at night, with perhaps eight seriously injured men in urgent need of trained attention—the simple, easily remembered routine with its scope for elasticity and improvisation under the immediate orders of the M.O. will steady the orderlies, whereas a more elaborate organization delegating complex individual duties to each member of the staff may break down.

Every orderly can, however, be trained in the essentials and rationale of anti-shock treatment, including the administration of morphine by tubunic ampoules, in the control of haemorrhage, the utmost gentleness in handling fractures, the preparation of a trolley for intravenous injection or anaesthesia, and the technique of sterilizing instruments and assisting at minor surgical operations. Above all they can be imbued with enthusiasm and a feeling of confidence and pride in their performance as a team under the guidance and leadership of their M.O.s.

Conclusion

Because of all this the M.O.'s job in the R.A.F. is an extremely important and responsible one. His knowledge of general medicine and surgery is by no means doomed to decline on a station; rather will he gain a breadth and background to his judgment, increased by the necessity for independent action and decision in many cases. He will encounter the special psychological problems of modern flying, and may gain personal experience of flight in modern operational aircraft. No matter how young he is, his position in the community of his brother officers is established; to them he is "the Doc."—to be consulted at all times and in all places. He is expected to advise his commanding officer on all matters relating to the hygiene and health of the unit—advice to which a good commanding officer attaches considerable importance and upon which he acts.

To the unit as a whole, the M.O.'s capabilities and attitude to his job are equally important. Service life has meant changes and sacrifices for them far more fundamental than those he has to accept—the diversion of his career and the severance, at any rate for some time, of his hospital connexions. He is bound still to follow his vocation; the least he can do is to display the utmost energy and enthusiasm for its every aspect.

The aspects that have been stressed here are perhaps less obvious than the more material and generally recognized responsibilities for the care of the sick and injured, the supervision of sanitation, and the keeping of medical records. But they are no less exacting; moreover, they are vitally important, because indifferent morale can rot the fittest body of men. The influence of a medical officer on the morale of his unit—the inescapable obligation for its upkeep that he shares with his senior officers—inspires with an Aesculapian touch his first duty: to maintain the effective strength of his unit by every means in his power.

AN INVESTIGATION INTO THE STANDARD OF MILK SUPPLIED TO CHILDREN

BY

ARTHUR G. WATKINS, M.D., M.R.C.P., B.Sc.

Lecturer in Paediatrics, Welsh National School of Medicine

The British Paediatric Association recently organized an inquiry into the standard of milk supplied to children throughout the country. It is felt that the findings would be of interest to the medical profession and should be made more widely known. This article is based on information so received from eight separate areas in England, Wales, and Scotland, representing a London borough, a Scottish city, a West of England city, a South Wales urban area and a South Wales rural area, two Northern industrial towns, and a Midland county. As the reports received were in the nature of confidential comments the areas are subsequently designated by the initial letters A to H.

Results of Questionaries

A questionary was sent to each area and the following is a summary of the replies received:

1. Is there any Evidence of an Increase in Bovine Tuberculosis in Children Since the War?

Area	Non-pulmonary Tuberculosis			
	1938	1939	1940	1941
A*	—	—	—	—
B†	120	126	107	143
C	30	36	29	54
D	No increase			
E	,, ,,			
F	,, ,,			
G	—	527	—	664
H	No increase			

* Double the number of cases of meningitis in 1938 as compared with 1941.

† From P.M. material: 1935–9, 15·7% primary abdominal; 1940–1, 58·3% primary abdominal.

Accurate evidence on this point has been difficult to obtain owing to the shifting population. Some observers report a clinical impression of an increase, especially of tuberculous glands in the neck.

2. Is there any Evidence of an Increase in Tuberculous Cattle Since the War?

Area A.—Samples of milk containing tubercle bacilli:
1938, 8%; 1940, 5·3%; 1941, 6%
Areas B, C, and D.—No evidence
Area E—Cases dealt with by Ministry of Agriculture and Fisheries:
1939, 267; 1940, 192; 1941, 164
,, F.—No evidence
,, G.—Samples of milk containing tubercle bacilli:
1939, 9·4%; 1940, 6·3%; 1941, 6·0%
,, H.—No evidence

Evidence on this point has been difficult to collect, as tuberculin testing has been reduced, slaughterhouse statistics are no longer reliable owing to different allocation of carcases by the Ministry of Food, and there is a shortage of inspectors.

3. Is there any Evidence of an Increase in Milk-borne Infections, other than Tuberculosis, Since the War?

Area A.—No evidence
,, B.—Increase in notification of undulant fever
Areas C, D, and E.—No evidence
Area F.—? Increase in gastro-enteritis due to milk?
Areas G and H—No evidence

In a personal communication Prof. G. S. Wilson of the Emergency Public Health Laboratory Service states that in the area covered by that service there have been two small outbreaks of undulant fever, three outbreaks of dysentery due to the Sonne organism (one of them involving over 1,000 people), two outbreaks of diphtheria, and one of typhoid fever, all due to the use of raw milk, and one of paratyphoid fever probably due to its use.

4. What Percentage of Milk is Pasteurized?

Area A.—70 to 75% sold as pasteurized
,, B.—40%—not all sold as such
,, C.—30%
,, D.—65%
Area E.—60%
,, F.—90%—only 50% sold as such
,, G.—80%
,, H.—40%

Several areas comment on two points: first, that not all pasteurized milk is sold as such; and, secondly, that any heat-treated milk is often erroneously referred to as pasteurized.

5. What Percentage of Milk is Sold Ungraded?

Area A.—12 to 15%
,, B.—70%
,, C.—50%
,, D.—32%
Area E.—?
,, F.—48%
,, G.—2 to 3%
,, H.—40%

6. Has the Bacterial Content of Milk Changed Since the War?

Area A.—Higher bacterial content. Pre-war, 10% pasteurized milk failed to pass test; post-war, as high as 50% at times
,, B.—Higher bacterial content One district reports samples over 100,000 orgs./c.cm.: 1938, 11%; 1939, 19%; first half 1940, 35%
,, C.—Higher bacterial content. One district reports: "Still as bad as ever"
,, D.—Higher bacterial content
,, E.—25% samples of "accredited" milk unsatisfactory
,, F.—Higher bacterial content
,, G.—No change
,, H.—Higher bacterial content

7. What Standard of Milk is Supplied to Nursery Schools and Day Nurseries?

Area A.—Pasteurized
,, B.—Variable
,, C.— ,,
,, D.—Pasteurized
Area E.—Accredited or pasteurized
,, F.—Pasteurized
,, G.— ,,
,, H.— ,,

8. What Standard of Milk is Supplied to Schools?

Area A.—Pasteurized
,, B.— ,,
,, C.—Variable
,, D.—Pasteurized
Area E.—Accredited or pasteurized
,, F.—Pasteurized
,, G.— ,,
,, H.—Variable

9. What Standard of Milk is Supplied to Children's Hospitals?

Area A.—Pasteurized or T.T.
,, B.—Variable
,, C.—Ungraded
,, D.—T.T.
Area E.—?
,, F.—Pasteurized
,, G.—T.T.
,, H.—Pasteurized

10 Do Welfare Centres Mainly Recommend Liquid or Dried Milk?

Area A.—Liquid
,, B.—Dried
,, C.— ,,
,, D.— ,,
Area E.—Liquid and dried
,, F.—Dried
,, G.— ,,
,, H.— ,,

11. What Proportion of National Dried Milk is Used?

Area A.—11%
,, B.—20%
,, C.—30%
,, D.—High proportion
Area E.—Hardly any
,, F.—55%
,, G.—Hardly any
,, H.—90%

12. Are You Satisfied with the Standard of Milk in Your Area?

Area A.—No
,, B.—No
,, C.—No
,, D.—Yes
,, E.—No
Area F.—Only one sample of pasteurized milk in 1942 failed to pass standard
,, G.—No—so long as 6% samples contain tubercle bacilli
,, H.—No

13. What Standard of Milk do you Recommend?

Area A.—Dried milk for infants; pasteurized for older children
,, B.—Dried milk up to 9 to 12 months old; pasteurized for older children
,, C.—Dried milk for infants; pasteurized for older children
,, D.—Good quality milk from a herd free from tuberculosis. All fresh milk to be scalded
,, E.—Dried milk or pasteurized
,, F.—Dried milk up to 12 to 18 months old; pasteurized for older children
,, G.—Dried milk for infants; pasteurized for older children
,, H.—T.T. and bacteriologically clean

Comments

In a field survey of this kind it has not been possible to obtain accurate figures, but, representing as it does the findings of paediatricians in their respective areas, it is disquieting to note that so many are dissatisfied with their milk supply. Comments received from medical officers of health also suggest that they too are concerned about the problem, with little if any power to correct matters. It would, however, seem possible for health authorities at least to ensure a safe milk supply for children in their nursery schools, day nurseries, schools, and hospitals.

The fact that certain areas report 6% samples of raw milk containing tubercle bacilli is a reflection on our cattle supervision, but it must not be forgotten that, although tuberculosis is perhaps the most serious of milk-borne infections, it is by no means the only one, and measures such as tuberculin testing of herds deal with only half the problem, and not too well with that half. There is no alternative to pasteurization, which alone can prevent all milk-borne infections.

The problem of efficient pasteurization is many-sided, and therein lie its difficulties. One medical officer of health reports that of three firms selling pasteurized milk in his area only one, as judged by the phosphatase test, is satisfactory, yet little attempt is made to bring offenders to book. If milk below the specified fat content is sold fines are readily imposed, but the selling of milk improperly pasteurized is too often ignored by legal, health, and sanitary authorities alike. Perhaps the commonest faults in pasteurization are inefficient cooling of milk at the farms and delay in transport to the pasteurization plants, both accentuated by wartime conditions. This can only be corrected by proper inspection by responsible authorities. To examine the plant only is not enough; if milk is to be pasteurized it must be of a sufficiently high standard of bacterial cleanliness, otherwise rapid souring may take place. As Wilson (*The Pasteurization of Milk*, 1942, London) says, "Though it may make a dangerous milk safe, pasteurization can never make a dirty milk clean."

That so little has been done by responsible authorities, including the Government, to tackle the problem of safe milk in spite of urgent recommendations by such bodies as the B.M.A., the Royal College of Physicians, and more recently the M.R.C. Committee on Tuberculosis in Wartime, is an indictment on our preventive-medicine policy. The M.R.C. Report sums up the situation by saying: "If all milk for human consumption were pasteurized in licensed plants under adequate supervision, it is no exaggeration to say that tuberculosis of bovine origin would be eliminated." Why, then, cannot this be done, with the example of the U.S.A. and Canada before us? In a personal communication Dr. Enid Williams says that in a small number of cases of tuberculous meningitis which she has investigated 50% were found to be due to the bovine bacillus. Here we have a fatal disease untouched by clinical therapy, yet preventable in a large proportion of cases by safe milk. There is no other field in which preventive medicine can hope to achieve such dramatic results. If the British Paediatric Association's findings can help to stimulate the powers that be to legislate for a safe milk it will have served its purpose.

Summary

The following recommendations have been made by the British Paediatric Association as the result of the above investigations, and have been forwarded to appropriate authorities:

1. All milk to be efficiently pasteurized. Increased inspection of cooling facilities on farms and pasteurization technique is essential.

2. These investigations revealed that the safeguards to ensure that pasteurization is efficient are not reliable, and it is recommended that steps be taken to remedy this state of affairs.

3. Until all milk is efficiently pasteurized the public should be instructed to scald all liquid milk for children up to 5 years of age, but preferably dried milk should be used for infants.

The services of the family doctor are to be called on as part of the Ministry of Health's campaign for the immunization of all children against diphtheria. The Ministry (Circular 2753) points out that, in response to its first appeal in the early part of last year, local authorities concentrated on school children and those of pre-school age attending maternity and child welfare centres, as the centres were the obvious places for immunization of the child population. But the time has come, the circular continues, to find out just which children in an area are not yet immunized, and for the local authority to make whatever arrangements are necessary to deal with the position. If for any reason a child cannot attend a centre, immunization should be carried out at home by the family doctor. Doctors should be asked to undertake this work, the local authorities informing them at the same time of the fee they are prepared to pay for the service. The prophylactic will be supplied in suitable containers free of cost. It is pointed out that this domiciliary immunization should not be regarded as precluding doctors from being employed at centres, but as supplementary to their work there.

Reports of Societies

RADIOLOGICAL DIAGNOSIS OF DISPROPORTION

At a meeting of the Section of Obstetrics and Gynaecology of the Royal Society of Medicine on January 15, Dame LOUISE MCILROY presiding, the subject of discussion was the radiological diagnosis of disproportion.

Prof. J. CHASSAR MOIR said that the question of fit or misfit, adjustment or maladjustment, was ever present in obstetrics, and radiology would solve some of the problems which remained obscure on clinical examination. Three radiological views of the pelvis were desirable, though with careful clinical examination one or even two of these might be unnecessary in a given case. The lateral view was by far the most important in any single examination. He proceeded to speak from an experience of 410 obstetric cases examined radiologically. This had been done in the later weeks of pregnancy, partly because he was reluctant to subject the young embryo to mass radiation, and partly because it was in the later stages that the foetal head could be better defined.

With regard to the value of cephalometry he found on an analysis of 82 cases that in 75 the forecast was correct to within 1 mm. over and 3 mm. below the stated figure. In 2 cases the head was less than the stated figure by more than 3 mm., and in 5 it exceeded the stated figure by more than 1 mm., but these were all cases of abnormally shaped heads. In approximately 90% of cases radiography gave a useful estimate of the size of the baby's head. He believed the growth of the foetal head to be from 1 to 1.5 mm. per week during the last weeks of pregnancy; this was borne out by measurements of the rate of growth after birth. The most important of the measurements in radiological diagnosis was the conjugate measurement of the brim. The pelvic brim should not be regarded as a kind of sieve, and it should not be thought that any head which could pass through the brim would also negotiate the lower reaches of the pelvis.

Maternity hospitals were increasingly asked to provide facilities for normal confinements, but there were also women who elected to be, but should not be, confined at home. It might be said that this should not happen if ante-natal examination were properly performed, but at present there were not enough ante-natal examiners. Radiology could differentiate between those patients in whom delivery would be easy and spontaneous and those in whom difficulty might arise. The time might come when all women entering their names for domiciliary midwifery would be radiologically examined as a routine. Patients who had an unreasonable fear of obstetric difficulty might be reassured by a radiological examination. Obstetric radiology had been criticized on the ground that it emphasized certain features of the birth process and ignored others which also played a major part in deciding the course of labour. But disproportion was one of the greatest causes of difficulty at birth, and it was here that radiological examination had its use. Some feared that the use of radiology would lead to unnecessary surgical intervention, and this was possible when bad radiology was combined with bad obstetrics; but a similar misgiving might obtain when radiology was used in examination of fractures and other conditions. Radiology had oftener influenced him against Caesarean section than in its favour. The obstetrician's clinical judgment was improved by the increased knowledge of the birth mechanism which radiology afforded. But it was not a short cut to the solution of every problem of birth mechanics. Some people endowed radiological reports with an infallibility which was quite mistaken, to the disadvantage of obstetrics and radiology alike. In its proper place obstetric radiology was a valuable adjunct to clinical methods.

Dr. E. ROHAN WILLIAMS said that his personal experience was virtually confined to ante-natal examination. In 1941 an *x*-ray department was opened at Queen Charlotte's, with facilities for the examination of out-patients, but the provision of an *x*-ray unit for the labour ward had been delayed by the war. The radiologist might be said to have a special responsibility when there was disproportion in the mid-plane or at the outlet of the pelvis. It was, of course, in borderline cases that the clinician was most likely to seek radiological help, and it was precisely in these that radiology might still leave the matter in doubt. It was in such cases that he had hitherto been too pessimistic about the value of radiology, but his own judgment had improved since charting in two projections—a method which he illustrated by means of a film—had been done as a routine. He believed that this charting offered a fair and reasonable basis for forming conclusions on the relative proportions of foetal head and pelvis.

Dr. CLARK NICHOLSON said that it was an advantage to have got away from the consideration of the shape of the pelvis and to consider its size only. He had been concerned with pelvic measurements now for ten years and had a series of over 700, mostly normal, cases, but he thought it quite reasonable to argue from the normal to the abnormal. The average foetal head entering the average maternal pelvis occupied no more than 55% of the area, and, from his calculations, if the proportion of the foetal head to the maternal pelvis exceeded 75% (or more probably 80%) the case might be defined as disproportion. Disproportion therefore could not arise in the average pelvis. But the foetal head was not the only part which could cause disproportion; the over-weight foetus was also a problem, quite apart from the size of the head. With regard to the outlet, the average measurement, taking the area of lowest pelvic diameter, was 108 sq. cm. Here the proportion of 80% did not hold good. The outlet was a different matter altogether from the inlet. He thought the outlet to be capable of enlargement, certainly much more than the inlet. The brim was more or less fixed; it could alter its shape a little but not its size, whereas the outlet could undoubtedly be enlarged by tilting of the bones which formed it. It was time to consider why disproportion arose at all. It was largely a question of pelvic contraction, and the governing factor was nutritional defect. If malnutrition were dealt with thoroughly disproportion would disappear very largely within the next generation.

FUNCTIONS OF THE PYLORIC CANAL

At a meeting of the Section of Anatomy and Physiology of the Royal Academy of Medicine in Ireland, with the president, Prof. J. F. DONEGAN, in the chair, Dr. J. W. MILLEN read a paper on the subdivisions of the stomach.

Dr. Millen said he wished to draw attention to the normal subdivisions of the human stomach, and, in particular, to the importance of the pyloric canal as a distinct region which differed in its anatomy, mobility, and function from the other divisions of the stomach. In the normal adult human stomach three primary parts could be recognized: (1) a region for reception and storage—this was the primary function of the stomach, and in this sense the stomach was present in all but the lowest invertebrates; (2) a terminal closure mechanism—the pyloric sphincter—which assisted in the maintenance of storage; (3) an active milling region—the pyloric canal—for the physical trituration and fine subdivision of food; this region was interposed between the first and second parts. The receptive storage region comprised the body and fundus of the stomach and a more or less well-defined part—the pyloric antrum—specialized for the active filling of the pyloric canal. *X*-ray photographs of the stomach of a young adult showed that in the early stages of canalization of the empty stomach by an opaque meal the food did not at once enter the pyloric canal. When a small amount of the meal was manually pressed into the pyloric canal the longitudinal folds of the mucous membrane could be seen in the canal, and the pyloric sphincter at its distal end was well defined. After about half a pint of the meal had been given further pictures showed that the pyloric canal had now become rounded and globular in shape, but was still distinctly recognizable as a separate region filled from the pyloric antrum by deep peristaltic waves which traversed it. In approximately one-third of the dissecting-room subjects examined no pyloric canal could be defined, the whole stomach consisting of a single cavity closed distally by the pyloric sphincter. In two-thirds of the subjects examined the normal subdivisions described above were to be found. The absence of a pyloric canal in the first group was thought to be due to its incorporation in the proximal part of the stomach, and this might represent a shift towards the single-chambered stomach of the adult carnivores. He concluded that the pyloric canal had, therefore, two functions: first, as an active milling region; and, secondly, in the emptying of the stomach, either as an active or passive region co-ordinated with the body of the stomach. Congenital hypertrophic stenosis of the pylorus—a hypertrophy of the pyloric canal and not of the pyloric sphincter—might, therefore, be due to the pyloric canal functioning as a mill, but failing to act in harmony with the proximal part of the stomach in its function as a part of the emptying mechanism.

Correspondence

“Calorie Control” Diabetic Diet

SIR,—Dr. A. C. Crooke and Miss Ella Scott have described (Jan. 16, p. 64) a “new dietetic treatment” of diabetes which so radically contravenes accepted dietetic principles and, still worse, the known physiological facts of insulin action on blood sugar and carbohydrate food, that I hurry to criticize the system and the statements therein. In a way I am glad it has been published because several patients on the scheme have been referred to me and I found them as mystified as I was.

The essential new feature in the scheme is the assumption that carbohydrate, protein, and fat (C.P.F.) have the same effect on the diabetic metabolism and are replaceable and equivalent in the diet if they contain the *same number of calories*. The diet prescribed is to be weighed to the last 1/4 oz. of butter, and an accurate list is given of the weights of all foods, C.P. and fat, containing 50 calories: 1/4 oz. of butter and 3/4 oz. bread (each 50 calories) are interchangeable, and it appears that the carbohydrate of any meal, usually thought necessary to balance the action of the insulin dose, can be replaced by protein and fat without any concern. “Thus a patient can take a protein and fat breakfast of bacon one day and a carbohydrate breakfast of cereal the next.” I know that my diabetic patients would develop serious hypoglycaemia if they replaced their breakfast carbohydrate by equicalorie protein and fat, and can hardly believe that Dr. Crooke can maintain the contrary. Does he really mean this or do I misunderstand him?

Dr. Crooke states that, although the new diet often requires more insulin, the glycosuria is less and insulin reactions are not increased; which latter fact surprises me if his patients apply C. ⇄ P.&F. substitution. But do these patients really follow and apply the principles of the diet? All the cases who have been referred or transferred to me had no scales, never weighed the diet, and did not understand or indulge in calorie exchange; they ate enough C. to buffer their large doses of insulin and followed, if anything, the sample diet in Table I. These may be exceptional cases, but as 1/4 oz. scales have hardly been available on the market since June, 1941, I do not see how the diet could be applied at home. Has Dr. Crooke provided the scales necessary for his scheme?

The article contains several statements and conclusions which it is impossible to appreciate as insufficient facts are given, and so I ask a few questions: (1) Results are given on a group of patients on the new and old diet, but the level of the new diet is insufficiently mentioned and the old not at all. What were they? (2) He states: “It has long been our custom to give patients who are not excessively obese a diet which corresponds as nearly as possible to that which each individual might be expected to take if he had not got diabetes.” Does this apply to the old and/or the calorie diet? If so, this sounds like a free diet (eat what you please), so why bother about a diet system and a weighed intake? (3) His insulin cases are classed as severe if on more than 60 units a day, as mild if on less. Surely this indicates the use of very large doses, as most people would call a case on 50 to 59 units a severe one, and the vast majority of my patients have under 60 units a day.

I have written many letters in your correspondence columns, but never before in such a critical and challenging spirit. But I feel that the fundamental principle propounded of unconcerned replacement of carbohydrate by equicalorie protein and fat is untrue and dangerous for insulin cases.—I am, etc.,

London, W.1. R. D. LAWRENCE.

SIR,—Dr. Lawrence is mystified by the simple diabetic diet which was described in your issue of Jan. 16 (p. 64). He asserts that the essential new feature of the scheme is the assumption that carbohydrate, protein, and fat have the same effect on the diabetic metabolism. This assumption was never made by me or any other thinking person. There can be no misunderstanding, however, that the diet is designed so that carbohydrate foods may be exchanged for protein or fat foods of the same calorie value within the limits of experiments described in our paper. These experiments were designed so that the daily variation in the proportion of carbohydrate to protein and fat exceeded anything that any ordinary patient might be expected to indulge in. He says that if his patients replaced their breakfast carbohydrate with protein and fat they would develop serious hypoglycaemia, but when our patients replaced their breakfast cereal with bacon or eggs no hypoglycaemic symptoms occurred.

Dr. Lawrence is worried because the new diet contravenes the accepted dietetic principles, but he ignores the fact that it has worked most satisfactorily in a series of 528 diabetic patients during the past eighteen months. The only exceptions have been a few patients with long-standing diabetes mellitus who refused to continue with it because it was against their own principles. Several of these have devoured all the bacon, eggs, and even butter that has come in for a household of 4 or 6 people, and they have been enraged when they have been told that this is unnecessary. Fortunately, these greedy people are very exceptional, but they so resent being given our new diet that perhaps Dr. Lawrence has met some of them.

Dr. Lawrence is also worried because the new diet contravenes the known physiological facts of insulin action on blood sugar and carbohydrate food, but he cannot have read the paper by Prof. Ellis referred to in our article. Prof. Ellis showed that when a patient's diet was changed from the ordinary type, in which the daily intake of carbohydrate, protein, and fat was kept constant, to a diet of 600 g. of glucose only for periods up to three weeks the patient's insulin requirement became progressively less. It is upon this physiological observation that the principle of the calorie control diet rests. Dr. Lawrence states that I said that patients on the new diet often require more insulin. His statement is misleading. Actually, patients' insulin requirements were found to have increased only when the value of their new diets exceeded that of their old ones by more than 50 calories. When the values of the new diets were the same as those of the old ones the patients were found to require less insulin than they would have done if their diets had never been changed. This is because they were able to take a relatively higher proportion of carbohydrate, and it is in keeping with Prof. Ellis's observations.

Dr. Lawrence asks for details of patients' diets. A typical example of an old diet for a working man would be carbohydrate 230 g., protein 90 g., and fat 80 g. This would usually be replaced by a new diet of 2,000 calories. These diets were tabulated for the 192 cases which were analysed, but the table was much too big to include in our article. Nor was it necessary to include it because we were concerned with the statistical results of treatment in three groups of cases. In the first group the new diet was more than 50 calories in excess of the old one; in the second it was within 50 calories of the old one; and in the third it was less than the old one by more than 50 calories. Dr. Lawrence then asks if it is not really a “free diet” when we give patients a diet which corresponds as nearly as possible to that diet which each individual might be expected to take if he had not got diabetes. This is obviously not so, for the whole object of the diet is to keep the calorie value of each meal constant from day to day. Finally, he objects to the classification of diabetes as severe when patients require 60 or more units of insulin a day and mild when they require less than 60 units a day. This classification is arbitrary, and was designed to see if there was any statistical difference in response of the different groups to treatment. It happened that all groups did equally well on the new diet.

We do not provide our patients with food-weighing scales. They are very difficult to get, but many patients have their own. We urge all those who have none to try to buy them in the local shops or to borrow them from friends. It would be interesting to know if Dr. Lawrence provides his patients with scales with which to weigh his own diets.—I am, etc.,

London Hospital A. C. CROOKE.

Dietetics of Pregnancy

SIR,—Will you allow me to make as briefly as possible some criticisms of your leading article entitled "Dietetics of Pregnancy" (Jan. 2, p. 16).

1. Your leader writer purports to quote the conclusions of Nixon *et al.* What they have shown is as follows: (*a*) In a group of toxaemic patients the mean rate of excretion of aneurin was significantly less than in a group of non-toxaemic patients. (*b*) In a group of toxaemic patients the mean aneurin concentration in the placenta was significantly less than the mean concentration in the placentas of a group of non-toxaemic patients. (*c*) They also showed, though they did not comment on this finding, that the mean weight of the placentas of this toxaemic group was roughly half that in the non-toxaemic group.

Since no attempt was made to discover how far the lesser rate of aneurin excretion in the toxaemic group was associated with deficiencies in renal function (which might reasonably be expected to be more frequent in this group than in the non-toxaemic group), the assumption tacitly made by Nixon *et al.*—that the lower mean rate of aneurin excretion in this group implies a difference in nutritional state—is certainly not proven. They use the data for aneurin content of the placenta to support the notion of aneurin deficiency in toxaemic patients, but they fail to draw attention to the fact that in a group of patients in which the mean placental weight is *half* normal the placentas are certainly not normal in constitution, and differences in concentration of a variety of chemical constituents are to be expected in such patently abnormal tissues, quite apart from any changes of nutritional state.

It will be seen that, although Nixon *et al.* have established relations of interest, their conclusions are not the only or even the most probable ones that can be drawn from their data. In any event, the extent to which they imply that aneurin deficiency may occur in toxaemia is that they say: ". . . It is suggested that vitamin B_1 might be beneficial to such patients." This appears in your leading article as: "Nixon, Wright, and Fieller, who find a highly probable correlation between suboptimal intakes of aneurin and the incidence of oedema and pregnancy toxaemia."

2. The qualifications of your leader writer for the critical appraisal of quantitative data are demonstrated clearly in the following passage dealing with the work of Williams and Fralin:

> "Their subjects, according to their own statement, failed to demonstrate 'any positive relationship between dietary adequacy and the occurrence of certain complications of pregnancy and childbirth'; *yet this is not altogether consistent with their observation that '84% of a group who presented a history of nausea and vomiting in early pregnancy had an intake below the pregnancy standard of 600 units of vitamin B_1.'* It must be noted, moreover, that of their 514 cases only 10 were receiving diets that 'could be termed good,' so that positive controls were largely lacking in this investigation."

The italics are mine. The figure of 84% may have a meaning when it is compared with the corresponding figure for patients not showing nausea and vomiting; but in view of the fact that 504 out of 514 patients in the series (i.e., 98%) are on diets that were not good, it seems probable that at least as great a proportion of those not suffering from nausea and vomiting might have been on a diet containing less than 600 I.U. of aneurin daily. There is, of course, the point that nausea and vomiting might more properly be called diagnostic features of early pregnancy, but this point is secondary to the present discussion.

3. Your leader writer experiences the same difficulties in dealing with figures in his treatment of the work of Tisdall and his colleagues. Numerous points of importance in the evaluation of this work seem to have escaped him. Some of them are discussed below.

(*a*) In the paper in the *Journal of Nutrition* the authors, in referring to the supplemented-diet group, say that they were "on an especially poor diet until the *fourth or fifth month* of pregnancy and then received extra food from us." In the paper in the *Canadian Medical Association Journal* they say (p. 2, col. 2): "90 women who were on poor diets until the *fifth or sixth month* of pregnancy and were then given extra food until 6 weeks after delivery . . ."; but in the summary of this paper they say (p. 5, col. 2): "Milk, eggs, tomatoes, oranges, and cheese were supplied to 90 of the women from the *fourth or fifth month* of the pregnancy until four weeks after discharge from hospital." The discrepancy between the second of these statements and the others is of some importance. The authors report a high frequency of "miscarriages" in the poor-diet group compared with that in the supplemented group. "Miscarriage" in this country denotes expulsion of the foetus before the 28th week of pregnancy. It occurs far more frequently before than after the end of the 4th month.

If miscarriage means to Tisdall *et al.* what it means in this country, the frequency of miscarriages in the period of the experiment is surprisingly high, even in the supplemented group, whether we take it that the supplementing began at the beginning of the fourth month for the majority of patients or at the end of the sixth month.

These weaknesses of definition are such that it is clear that the data are not fit to indicate relationships of importance in this field, let alone to support any edifice of policy.

(*b*) Tisdall *et al.*, in the regrettable clinical fashion, present their results as percentages. Any of your readers who has had the curiosity to convert the percentages referred to in your leading article into numbers of cases will have come across a puzzling and unsettling phenomenon. The figures reproduced by your leader writer for the numbers of patients in the groups (120 poor diet, 90 supplemented, and 170 good diet) are correctly reproduced, as are the reprinted percentage frequencies of threatened miscarriage, actual miscarriage, premature birth, stillbirth, and toxaemia. But when an attempt is made to derive the actual number of cases falling into each category, we have:

	Poor	Supplemented	Good
Threatened miscarriage	10	1	4
Actual miscarriage	7.2*	0	2
Premature birth	9.6*	2	5
Stillbirth	4	0	1
Toxaemia	9.1*	3	5

In the instances marked with an asterisk the percentages given by Tisdall *et al.* are given to two significant figures (6.0, 8.0, and 7.6 respectively), whereas, if there were 7, 9, and 9 cases in these categories, the percentages should have been 5.8, 7.5, and 7.5 respectively. It is curious that these differences should have occurred only in the poor-diet group: they certainly suggest that the data as presented are not to be relied on.

Three other features of this table are of importance. First, instances of different *complications* and not of *patients* are entered in it. There is no telling what proportions of the patients in the different groups suffered from complications of pregnancy. The experiment was one in which women and not complications were fed. Secondly, the good-diet group is not to be compared with the others as instancing the effects of diet, since it comprised patients whose social and economic status were generally better than patients in the poor and supplemented groups. Thirdly, it appears from consideration of the data in this table that the whole evidence on which Tisdall *et al.* can rely as showing an effect of diet on the complications of pregnancy is that in the first two columns of the table. It has already been indicated that their definition of miscarriage would appear from the evidence to differ from the English one. If it does not, then any effect of the supplementing of diet on the frequency of miscarriages must have been more magical than nutritional. As for the remaining complications—premature birth, stillbirth, and toxaemia—it would seem that an elementary knowledge of the subject would indicate that more than one of these was likely to coexist in the same patient. There is no way of telling from the data presented by Tisdall *et al.* whether or not in the poor-diet group these figures refer to as few as 9 patients who exhibited two or more of these complications or as many as 23 who exhibited one each. Similarly, in the supplemented group there may have been as few as 3 or as many as 5 patients exhibiting complications. This, then, is the evidence, so far as it can be dignified by the name, for the effect of diet on the complications of pregnancy which is presented in this "highly significant" survey. This consideration of the figures of Tisdall *et al.* is not an exhaustive one. There are sundry other inconsistencies in their work which effectively undermine any confidence one might have initially been inclined to feel in their data.

The work of the People's League of Health has been dealt with ably and forcibly by Doyne Bell in a discussion at the R S M., and has been reported in your columns; I would refer your readers to the full report in the current issue of the *Proceedings of the Royal Society of Medicine.*

The most disturbing feature of the current treatment of this subject of dietetics in pregnancy is the irresponsibility displayed by a section of the medical profession in a matter affecting a vital aspect of public policy. To begin and to perpetuate a clamour for better feeding in order to diminish the hazards of pregnancy is a laudable object if there is evidence that it is a real object. But to do so irresponsibly on "evidence" of the sort so far presented, at a time when the satisfactory feeding of the people as a whole calls for all the skill of a skilful organizer, is tantamount to an act of sabotage of the first magnitude. It is for this reason that I have felt it was imperative to combat the impression conveyed by your leading article of the state of knowledge of the effects of diet on the incidence of the hazards of pregnancy.—I am, etc.,

Department of Biochemistry, Oxford R. B. FISHER.

Pituitary Extract for Congenital Pyloric Stenosis

SIR,—I should like to report a case of congenital pyloric stenosis cured by treatment with anterior-pituitary-like hormone. On Sept. 26, 1942, a woman of gipsy extraction gave birth to a healthy male child weighing 6 lb. 15 oz. Delivery was normal. At first the infant sucked well, but after three days he showed increasing incompetence at feeding and increasing tendency to vomit. The vomiting became projectile. At 10 days he vomited after every third feed, and on the 11th day he vomited a large projectile vomit after alternate feeds. His loss of weight was 1 lb. 12 oz. He was lethargic and looked ill.

On Oct. 8, 1942, Mr. John Levis of Bath saw the child. He and two other observers felt the tumour typical of congenital pyloric stenosis. He ordered the treatment he had studied, which had been used with striking success in Geneva before this war—namely, injections of 7½ rat units of pregnyl on Oct. 8, 15 r.u. on the 10th, 22½ r.u. on the 12th, 30 r.u. on the 14th, 16th, and so on. The child vomited once on the 9th, once (small amount only) on the 11th, and once on the 12th. On Oct. 10 he ceased to lose weight, and on the 11th he had gained 1/2 oz. Subsequently he continued to gain at an increasing rate. He began to have an appetite on about Oct. 18, and was discharged looking well and feeding well on Oct. 22. He had no further treatment. He was seen by the sister (who had taken such excellent care of him in hospital) in December, and was still well.—I am, etc.,

Trowbridge. E. CURPHEY.

A Case of Balantidiosis

SIR,—In view of the recent articles on intestinal infections in the *Journal*, I feel that a short account of one of my patients in a mental hospital will be of interest.

The patient, a man aged 71, was suffering from an infection which, from its rarity, is of more than common interest—namely, balantidiosis. He was a "ground parole" patient, and found that the occupation most congenial to him was the care of the piggery on the hospital farm. He had been working in this capacity for some little time, when, on June 29, 1942, he complained of loose motions. The stools were examined in the laboratory for dysentery bacilli (as dysentery had been fairly common), but *Balantidia coli* were found. Obviously he had received contamination while working among the pigs.

He was removed at once to an isolation ward, and 1% methylene blue enemata, in doses of one pint, were administered on alternate days, commencing on July 7. The faeces were examined daily in the laboratory and showed balantidia constantly present. On the suggestion of the deputy medical superintendent, Dr. J. E. Howie, a course of artificial pyrexia was given by intravenous injections of pyrifer on alternate days commencing on Sept. 19. The course consisted of eleven injections, the highest temperature reached being 104° F. As before, the faeces were examined during the therapy, and showed gradually decreasing numbers of balantidia until on Oct. 12 these were entirely absent. Loose motions again made their appearance on Dec. 5, and further investigation of the stools showed numerous protozoa once more.

Owing to the inability of obtaining fresh supplies of methylene blue under war conditions, at least for some time, an empirical course of sulphaguanidine was given in the recognized doses according to body weight, beginning on Dec. 11. The stools showed no organisms on Dec. 17, but these reappeared on Dec. 21. With the arrival of fresh supplies of methylene blue, and acting on the suggestion of Mr. Bean, in charge of the laboratory, a further course of enemata, in doses of one quart, was begun on Jan. 5, 1943. Unfortunately, the patient had relapsed mentally, and was unable to retain such a quantity in the bowel, which had been given in the hope of reaching the organisms in the more remote diverticula and crypts of the gut.

For a short time before this last course of treatment he had been showing increasing signs of cardiovascular degeneration (which had been present for some little time), and he succumbed to this condition before a full trial of the treatment could be completed. The last stools, obtained the day before his death on Jan. 8, showed no balantidia, and a specimen of the contents of the transverse colon taken at a post-mortem examination revealed mucus, pus, and blood cells but no organisms or cysts. As the post-mortem examination was performed more than twenty-four hours after death, the presence of the organisms was not to be expected.

To sum up, the efficiency of the last treatment is indefinite, and cannot be judged accurately owing to death occurring before treatment could be completed, although disruption of the protozoa was marked with methylene blue *in vitro*.—I am, etc.,

County Mental Hospital, Warrington, Lancs.
P. A. M. ROBERTSON, Assistant Medical Officer.

Mitral Systolic Murmurs

SIR,—In his interesting paper on mitral systolic murmurs (Jan. 2, p. 8) Dr. William Evans does not mention the pulmonic second sound as useful in estimating the significance of a mitral systolic murmur. If there is no accentuation of the pulmonic second sound there is no mitral regurgitation; if there is accentuation, and especially if reduplication as well, the mitral murmur is important.—I am, etc.,

Hove. WALTER BROADBENT, M.D., F.R.C.P.

Skin Diseases in War

SIR,—I am prompted by my correspondence to make two brief comments on my article in the war medicine series (Dec. 26, p. 760).

In the first place I do not advise sulphanilamide or its derivatives in the treatment of the common varieties of impetigo, which respond quickly to mild antiseptics in lotions, creams, or pastes. Sulphanilamide has no demonstrable effect upon the brief course of the disease. In the exceptional case the indication for the use of sulphanilamide amounts to subclinical erysipelas, and this is clearly stated.

In the second place the Editor's note that the paper was based on a lecture recently given is misleading, because, in fact, the article was based on lectures given in 1941, was mostly written in that year, and submitted in January, 1942. This contretemps is only unfortunate as it affects the discussion of the treatment of scabies, and although the Editor kindly allowed me to insert a brief reference to the official emulsion of benzyl benzoate, it was not possible without rewriting the whole paragraph to give adequate prominence to the effective technique described in the memorandum on scabies and published by the Ministry of Health in June, 1942. Benzyl benzoate emulsion is undoubtedly the best and most elegant cure for scabies, but it is hoped that the discussion on the principles of treatment will be helpful when substitutes have to be used.—I am, etc.,

London, W.1. REGINALD T. BRAIN.

The Specialist in Medicine

SIR,—In the *Journal* of Dec. 26 (p. 764) the opinions of the Group of General Surgeons of the Johannesburg General Hospital on specialists are recorded. These views are uncomplimentary to specialists, who are said to be prone to a "somewhat confined outlook and lack of broad perspective," and it is suggested that in dealing with disease manifesting itself in a part of the body they do not pay due consideration to the whole organism.

I venture the opinion that these observations are based on the most slender justification, if any. In my experience specialists are very much alive to the relationship of one organ or part to the body as a whole, and are also familiar with the difficulty of persuading many of those who do not regard themselves as specialists that disease which is locally manifested has nevertheless always a general significance. "General" surgeons and, perhaps more especially, "general" physicians have by no means a monopoly of wide outlook and broad perspective, while they themselves are far from immune to the shortcomings attributed to more restricted specialists. The specialist who devotes himself to a particular organ or system does not regard disease disclosing itself in that organ as a disease of that organ but as a local manifestation of some general disorder.

In his textbook on the eye, Von Beer, the teacher of MacKenzie, "the father of English ophthalmology," wrote as long ago as 1813: "Everything that acts upon the whole acts also upon the part, and everything that acts upon the part must also act upon the whole; therefore everything that acts upon the organism of an individual cannot remain without action upon the eye and vice versa" (Von Beer, *Die Lehre von den Augenkrankheiten*, Vienna, 1813. Von Beer was a specialist, and there is a tincture of holism in his words that should appeal to South African surgeons.

The tendency towards isolation and canalization is a product of the development of medical practice and is liable to affect all doctors in greater or less degree. It is not the fault of any class of practitioner, but is inherent in the system under which the practice of medicine is at present conducted.—I am, etc.,

Edinburgh. H. M. TRAQUAIR.

Electric Convulsion Therapy and Brain Damage

SIR,—In reply to Dr. F. T. Thorpe (Jan. 2, p. 23) I would suggest that if the application of x volts to a criminal in the electrocution chair can destroy the most stable centres of heart and respiration, it is a logical conclusion that any considerable fraction of x volts would still do damage to the more delicate and vulnerable neurons and centres. This would account for the impairment of intelligence which many have noticed after electrical treatment, and other symptoms. Since the application of electrical treatment has moved from schizophrenia to involutional melancholia, it has been said that impairment of intelligence does not matter in these old people.

The New York State Hospital have treated 1,000 schizophrenics with insulin, 1,000 with convulsions, and kept 1,000 controls without treatment. The insulin group did three times as well as the controls, and the untreated controls did better than the convulsion group. The ratio between the insulin recovery rate and that of the convulsion group was nearly 7 to 1. As electrical convulsion treatment leads to impairment of intelligence, so does removal of part of the frontal lobe convert a patient who might possibly recover into a mental deficient. Personally, I prefer to use the combination of histamine and insulin.—I am, etc.,

Salisbury. HORACE HILL.

Testing for Night Vision

SIR,—With reference to the articles by Major B. W. Rycroft (Nov. 14, p. 576) and Mr. N. Bishop Harman (Jan. 9, p. 43) I think it should be stated that the instrument used by Major Rycroft was designed for the Military Personnel Research Committee of the Medical Research Council by Dr. K. J. W. Craik. The intensities of illumination are accurately calibrated, and if the instrument is used meticulously according to the instructions drawn up by Brigadier Sir Stewart Duke-Elder and issued to those concerned the results are strictly comparable.—I am, etc.,

Leeds. J. HERBERT PARSONS.

Staffing Mass Miniature Radiography Units

SIR,—My own practical experience of this problem, so far as the medical staffing of each available portable unit is concerned, shows that Dr. Norman P. Henderson (Jan. 16, p. 81) would appear to raise difficulties which should never exist. The experienced chest physician working in close co-operation with a similarly experienced radiologist with specialized knowledge of chest disease is an indispensable and essential team for the staffing of each unit. The two are complementary and in no way antagonistic. Their independent opinions on each technically satisfactory miniature film are the only real safeguard for the individual subject in mass work of this nature. Such experienced workers will obviously refuse to express an opinion on any film whose quality is not satisfactory, and they will wisely safeguard against this by the inclusion in their team of a first-class technician.

Clark, Cordiner, and I, working as a team of technician, radiologist, and physician in 1940 and 1941, co-operated in an experimental study with direct radiographs as controls. Our results have already been recorded (*Brit. J. Radiol.*, 1941, **15**, 54). Subsequently I had the privilege of co-operating with two experienced radiologists, Drs. Courtenay Gage and Poullsen, again with direct radiograph controls. My findings were compared with the independent interpretation of these radiologists and the results of the analysis have already been recorded (*Proc. roy. Soc. Med.*, 1941, **34**, 595). From these experiences I am convinced that an essential need for the staffing of each unit is: (1) the close co-operation of chest physician and chest radiologist interpreting films independently and scrutinizing results conjointly; and (2) a first-class technician with additional assistants properly trained and experienced. The numbers examined must of necessity depend upon the accommodation, assistants, and dressing space available.

The claim of Continental workers that these examinations can be carried out at a rate of 300 or more per hour would not appear from personal experience to be compatible with good quality films, which are surely of greater importance than speed.—I am, etc.,

PHILIP ELLMAN.

X-ray Department at Health Centre

SIR,—Dr. Brailsford's letter (Jan. 16, p. 83) suggests an answer to many of the questions about which he is still in doubt.

1. I think it is not only advisable but essential to equip every health centre with apparatus suitable for conducting all routine examinations for all patients, irrespective of their size and build.
2. I do expect every centre to have the services of an expert radiologist.
3. I do not deprecate the transfer of patients from one centre to another for further investigation, but rather hope that when transferred they will go with radiological evidence that will be comparable with that obtainable in the parent hospital.
4. Miniature mass radiography will be unlikely to miss the early active case of phthisis, and there is certainly no slur to be cast on the medical examination which missed it without radiological aid.
5. Miniature mass radiography will discover the tuberculous lesion arising in a patient within three to six months of an initial negative radiograph at the second routine miniature examination, should the patient's symptoms not have developed sufficiently to cause him to have consulted his doctor in the intervening period.
6. Radiology is a clinical method which should always be used in conjunction with other clinical methods.
7. To say that a chest lesion is of no significance until it is associated with clinical signs sounds untrue, and the signs, if present, may be insufficient to have caused the patient to seek medical aid.—I am, etc.,

London, S.W.3. J. V. SPARKS.

Search for Health

SIR,—In view of the lack of response from competent authorities I should like diffidently to correct a misapprehension on the part of Prof. J. A. Ryle in his most instructive article on the science of health (Dec. 26, p. 746), in which he deplores the lack of an "observational science devoted to the fireside or field-side or laboratory study of health." In fact, such a scientific study of health was inaugurated as long ago as 1926 in the Pioneer Health Centre, Peckham, which, after nearly three years of encouraging trial, was successfully continued on a larger scale from 1935 until the beginning of the war. You gave a short summary of its working a week before the publication of Prof. Ryle's article (Dec. 19, p. 735).

The primary purpose of the Pioneer Health Centre was to seek the answer to Prof. Ryle's question, "What is health?" Prof. Ryle's own answer makes health synonymous with wholeness. But this definition later leads him into the trap of referring to "the preservation of health," a phrase implying its previous attainment, which is clearly impossible for mankind if it denotes complete wholeness, physical, mental, and spiritual. If health equals perfection it must always be beyond man's imperfect grasp. The Pioneer Health Centre, on the other hand, suggests that health is not a state but a process: "the smooth progressive process of synthesis . . . the expression of the adaptative function of the organism operating progressively upon the extrinsic medium—the environment" (*Biologists in Search of Material*, 1938, p. 90; Faber). The attainment, rather than the process, of such a synthesis clearly equals Prof. Ryle's conception of wholeness; so that wholeness becomes the goal instead of the equivalent of health.

In order to test the validity of this dynamic conception of health the Pioneer Health Centre provided an environment "for the more intimate study and measurement and cultivation of health" in those families availing themselves of its facilities. A regular family overhaul and consultation provided the essential base-line for the estimation of the degree of health development brought about by use of the Centre's athletic and social amenities, as well as uncovering a wealth of previously undiagnosed ill-health. Therefore, in exploring the means "to teach health and the causes of health and the necessary provisions for health," Prof. Ryle will surely find a guiding hand in the idea and accomplishments of the Pioneer Health Centre.—I am, etc.,

Oxford. S. J. G. SPENCER.

Pasteurization of Milk

SIR,—May I through your pages offer Prof. L. P. Garrod (Jan. 16, p. 80) the information that streptococcal mastitis, in both acute and chronic forms, is one of the commonest infections of the cow, that human infection from this source is very rare, but that local lesions in the udder, caused by streptococci from human beings, may contaminate the milk. Sir William Savage, formerly M.O.H. for Somerset, has done good work in the investigation of streptococci in milk. Prof. P. S. Minett of the Royal Veterinary College says that this hypothesis of Sir William Savage's—that streptococci originating from human beings produce mastitis in the cow—has received a good deal of support from observation and experience, "so much support indeed, that it could not be doubted it was correct" (*Proc. roy. Soc. Med.*, Feb., 1937). Dr. F. Griffith of the Ministry of Health isolated scarlet fever (Type II) from milk in the Doncaster epidemic of 1936-7. During a period of six weeks six samples contained these streptococci (*Journal*, 1937, **1**, 519).—I am, etc.,

A. H. MACDONALD.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

Dr. M. F. Perutz is giving a course of lectures with demonstrations on "Methods of *X*-ray Analysis and their Application to Biological Problems," on Fridays at 5 p.m., in the Molteno Institute of Biology and Parasitology.

The title of the degree of M.D. has been conferred by diploma on Mrs. C. M. Hall, of Newnham College.

NATIONAL UNIVERSITY OF IRELAND

UNIVERSITY COLLEGE, CORK

The following candidates have been approved at the examinations indicated:

M.D.—B. J. O'Driscoll

M.B., B.Ch., B.A.O.—*D. F. Thomas, *K. V. J. Kearney, *W. P. F. Kearney, *P. J. Galvin, A. J. Beckett, E. Breen, J. Burke, T. Burke, M. F. Cahill, M. J. Collins, P. F. Corkery, M. J. Cosgrave, N. J. Dinan, R. J. Fitzgerald, Rose MacAuliffe, M. McCarthy, M. B. Millerick, D. Moroney, J. D. Morrissey, E. D. Murphy, C. O'Brien, Geraldine O'Callaghan, Maureen O'Driscoll, D. Ollivere, J. Osborne, H. P. J. O'Shea, R. F. O'Sullivan, Eileen M. Ring, J. R. Ryan, D. B. Sheehan, W. J. Shinkwin, M. J. Twomey, Mary T. Woods. *Part I:* Mary P. Moroney, J. O'Mahony. *Part II:* J. I. Buckner, L. J. Collins, T. A. Collins, Muriel C. Hurley, Maire MacCurtain, D. Murphy, B. O'Brien, J. J. Sheehan, J. J. Twomey, Winifred A. White. *Exempt in Mental Diseases:* T. Barrett, J. J. Sheehan, Winifred A. White. *Exempt in Pathology:* T. Barrett, Muriel C. Hurley.

D.P.H.—Abina T. O'Connor.

DIPLOMA IN PSYCHOLOGICAL MEDICINE.—T. McCracken.

* With first-class honours.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

At a quarterly meeting of the Council, held on Jan. 14, with Sir Alfred Webb-Johnson, President, in the chair, Mr. J. Newman Morris, F.R.A.C.S., was introduced and conveyed to the Council a message of greetings from the Royal Australasian College of Surgeons, which was cordially reciprocated. A resolution of condolence was passed on the death of Mr. L. R. Braithwaite, Vice-President, and the death of Dr. G. W. Crile, Hon. F.R.C.S., was reported. Mr. H. S. Souttar was elected Vice-President for the remainder of the collegiate year. Brigadier W. H. Ogilvie and Mr. L. E. C. Norbury were appointed representatives of the College on the Council of the Imperial Cancer Research Fund. It was decided that the first notice of the Council election should be published in the medical journals, as in 1942, and not sent by circular to Fellows resident in the United Kingdom, and that the second notice enclosing the ballot papers should be circulated as usual. All changes of address should be notified to the secretary. Communications in regard to the institution of the research chair in ophthalmology were received from the Council of British Ophthalmologists and from the joint committee of the ophthalmic hospitals in London.

A Diploma of Membership was granted to R. H. Maudsley.

Diplomas in Psychological Medicine were granted, jointly with the Royal College of Physicians of London, to the following successful candidates:

F. S. Adams, A.-el-A. M. Askar, C. Bard, Jean Durrant, Ada Glynn, E. C. O. Jewesbury, F. Post, Constance D. Roberts, P. H. Tooley, J. W. Wigg.

Diplomas in Laryngology and Otology were granted, jointly with the Royal College of Physicians of London, to the following successful candidates:

E. Benjacar, W. D. Doey, J. B. M. Green, B. L. Harbison, H. Mower, D. D. Steele-Perkins, W. M. L. Turner.

SOCIETY OF APOTHECARIES OF LONDON

At a recent meeting of the Court of Assistants, Sir Stanley Woodwark, Master, presiding, a letter of thanks was received from the University of London upon the completion of the Society's donation of £500 towards the cost of building the Ceremonial Hall of the University. A legacy of £50 to the Widows' Fund from the estate of Mrs. Freeman, widow of Past-Master Col. E. C. Freeman, was reported. A report on the recent session of the General Medical Council was made by Dr. J. P. Hedley, the Society's representative. The practical sections of the revived pre-medical examination were held at St. Mary's Hospital on January 7. Brigadier H. C. Edwards, Examiner, and A. G. S. Bailey, Licentiate, were Admitted to the Freedom of the Society by Redemption. Ralph Jordan Dodds was Bound Apprentice to Prof. E. C. Dodds for seven years.

The following candidates have satisfied the examiners in the subjects indicated:

SURGERY.—K. M. Donahue, J. H. Dransfield, M. A. Hamdy, E. E. Leiber, M. V. Matthew, R. Webb, C. E. C. Wells, R. A. Bush, D. B. Lawrence, J. M. Macdonald, J. M. Thomas, L. N. Yhap.

MEDICINE.—H. Gottschalk, H. V. T. Payne, J. H. Dransfield, J. A. Dryden, C. E. P. Grocott, E. R. Jones, W. C. Salter, C. E. C. Wells, L. N. Yhap.

MIDWIFERY.—F. G. Brindley, D. Headley, A. F. Rogers, J. H. Scarlett, J. M. Hanson, J. J. Maskell, C. E. C. Wells, L. N. Yhap.

The diploma of the Society was granted to J. A. Dryden, C. E. P. Grocott, E. R. Jones, E. E. Lieber, M. V. Matthew, W. C. Salter, C. E. C. Wells, R. A. Bush, L. N. Yhap.

Obituary

T. W. E. ROSS, M.D., F.R.C.S.ED.

We regret to record the death in Edinburgh on Jan. 14 of Dr. T. W. E. Ross at the age of 63. Educated at George Watson's College and Edinburgh University, Thomas William Edmondston Ross graduated M.B., Ch.B. with honours in 1902. After holding appointments as house-physician and house-surgeon at the Royal Infirmary of Edinburgh and the Maternity Hospital, he went to Vienna for further study. On returning to Edinburgh he took his M.D. and the Fellowship of the Royal College of Surgeons. For the next five years he was in practice in Cardiff, and at the end of that time he spent a year in Edinburgh studying diseases of the ear, nose, and throat under the late Drs. Logan Turner and J. S. Fraser. He began his general practice in Edinburgh in Morningside district in partnership with Dr. R. M. Ronaldson, and when the latter retired he moved into the centre of the city. For many years he has been one of the busiest doctors in the city, having a large and widespread practice. He was also principal medical officer to the Scottish Insurance Corporation. In the last war he joined the R.A.M.C. with the rank of captain and was with the Edinburgh Hospital at Salonika for some time. He was responsible for the radiological work in that hospital, and at the end of the war was awarded a decoration of the Order of St. Sava by the Serbian Government. In this war he not only took his share in the examination of recruits but was in charge of a first-aid post.

Dr. Ross was a man of sterling qualities. Under a somewhat rugged exterior was hidden a kindly and strong personality. His rather abrupt manner might be prejudicial at a first meeting, but his patients soon got to know that this was only on the surface and beneath was a man who was thorough and earnest in his work and who inspired confidence and trust. There are many in Edinburgh who will long mourn him, not only as a physician but as a friend to be consulted in difficulty. He had always been a hard worker and everything he undertook he did thoroughly. He never spared himself, and died as he would have wished, busy with his work to the very last. His chief recreation was golf, but he was also interested in music and general reading. His wife, who was a daughter of the late Rev. George D. Low of Fountainbridge Free Church in Edinburgh, died some years ago. He is survived by two daughters and a son, who is now serving abroad as a captain in the R.A.M.C.

R. C. L.

Dr. JOHN MORGAN REES of Pontypridd, who died on Dec. 29, 1942, in his 79th year, was the senior practitioner in the district. Educated at Queen's College, Taunton, and King's College, London, Dr. Rees took the M.R.C.S. and L.S.A. in 1887. He began practice as assistant to the late Dr. Webster at Merthyr Tydfil, and it was while he was there that he was awarded the diploma of the Royal Humane Society for rescuing a youth from drowning. Dr. Rees started practice on his own account at Pontypridd in 1897, and became one of the leading practitioners of the district. His interests were varied; proceedings of the Cardiff Naturalists' Society, archaeology, Welsh folk-lore and literature occupied his leisure. His chief interest, however, was in the practice of his profession and in the welfare of its members. He was a faithful member of the B.M.A. for 54 years, the offices he held including that of chairman of the North Glamorgan and Brecknock Division in 1916-17 and president of the South Wales and Monmouthshire Branch in 1927-8. He was a representative at five Annual Representative Meetings, a member of the Welsh Committee for many years, and in 1927-8 was a member of the Central Arrangements Committee in connexion with the Annual Meeting at Cardiff. He was also on the Glamorgan Panel Committee from its inception, and at the time of his death was the treasurer; he was one of its representatives at the Panel Conference. No meeting of medical men in the county of Glamorgan was complete without Dr. Rees, and it can be said that he was one of those who succeeded in promoting professional amity in this part of South Wales. His death removes one of the old type of medical men—a cultured gentleman, dignified, and always courteous. He married Miss Gladys Enid Jones, who, with one daughter, predeceased him. He is survived by another daughter and two sons, both medical men: Dr. Llewelyn Rees of Cardiff and Dr. Edward J. Rees of Pontypridd, vice-president of the local B.M.A. Division.

Correction

The late Dr. F. J Allen was a scholar of St. John's College, Cambridge, not a Fellow as stated in the obituary notice in the *Journal* of Jan. 16 (p. 86).

The Services

The A.F.C. has been awarded to Flight Lieut. B. J. O. Winfield, R.A.F.V.R.

The following medical officers have been mentioned in dispatches: Air Commodore T. J. Kelly, M.C.; Group Capt. R. W. White; Wing Cmdrs. G. P. O'Connell, Ll. C. Palmer-Jones, H. Penman, A. A. Townsend, H. H. S. Brown, and E. W. R. Fairley, R.A.F.; Wing Cmdr. D. H. Brinton; Squadron Leaders R. G. E. Richmond, A. Wilson, E. O. Evans, J. H. P. Gauvain, G. R. Gunn, J. R. O'Dowd, C. G. Rob, T. E. Whitby, J. R. Caldwell, and T. M. Prossor; Flight Lieuts. P. J. Blaxland, P. M. Davies, H. F. M. Finzel, A. J. Nimmo, W. L. Price, A. A. Smith, C. E. Waterman, and Flying Officer O. T. Brown, R.A.F.V.R.; Squadron Leader J. B. Murphy, R.A.F.O.; and Squadron Leader H. J. Riley and Flight Lieut. J. E. La Frenais, A.A.F.

Temp. Surg. Lieut. R. D. Wilkins, R.N.V.R., has been mentioned in dispatches.

Prisoners of War.—Lieut.-Col. C. Armstrong, M.B.E., R.A.M.C., Capt. A. D. Aveling, R.A.M.C., Capt. A. E. Brewer, R.A.M.C., Major H. M. Marks, R.A.M.C., Lieut.-Col. C. V. D. Rose, I.M.S.

Medical Notes in Parliament

Private Practice of Alien Doctor

On Jan. 19 Sir ERNEST GRAHAM-LITTLE asked the Home Secretary under what regulation or other legal provision he was withholding from an alien medical practitioner possessing a registered British medical qualification permission to engage in private practice in a certain town, on the ground that this practitioner acted for some months as an assistant to a doctor there without entering on any agreement restricting him from subsequent independent practice; and whether he was making it a condition that duly qualified foreign doctors who wished to practise in this country must join the B.M.A. voluntary scheme for local protection of practices. Mr. H. MORRISON said that, as he informed Sir Ernest Graham-Little in October, he did not feel justified in agreeing that the Austrian doctor to whom he referred should be allowed to establish himself in private practice close to a practice in which he had recently been employed as an assistant, but he had now approved of the doctor setting up in practice in a town some distance away. The answer to the second part of the question was in the negative, and he was taking steps to correct a misapprehension on this point to which Sir Ernest had drawn his attention.

Mines Medical Service

On Jan. 19 Mr. J. GRIFFITHS asked the Minister of Fuel and Power what progress had been made with the establishment of a medical service in the regions. Major LLOYD GEORGE said that a selected number of candidates from the long list of applicants for regional posts in the Mines Medical Service were being interviewed this week, and appointments would be made as soon as possible. Meanwhile, the Miners' Welfare Commission, in consultation with the Ministry of Health and the district welfare committees, had been actively engaged in the search for suitable buildings for miners' rehabilitation centres. A centre in Scotland, to accommodate 200 miners, was opened on Jan. 11, and the rehabilitation centre at Berry Hill had been taken over by the Miners' Welfare Commission from the Mutual Indemnity Company. Negotiations were in progress for the acquisition of buildings elsewhere, and good progress was being made generally in the other work involved in setting up centres to cover all the chief coalfields.

Mr. RHYS DAVIES observed that the Minister could be congratulated on finding so many doctors for this purpose, when the Minister of Pensions declared that he was unable to find doctors for his pensions tribunals. Sir FRANCIS FREMANTLE: Will the Minister consider consulting the Central Medical War Committee as to the disposal of man-power in the Forces in making these appointments, so as not to choose people who ought to be called up for the Forces? Major LLOYD GEORGE replied that the Ministry was in constant touch with all these authorities. Dr. HADEN GUEST asked how many doctors were being appointed. Major LLOYD GEORGE said he believed 8 would be appointed in the regions and 1 at headquarters—9 altogether.

Jamaica Medical Service

On Jan. 19 Mr. D. ADAMS asked the Secretary of State for the Colonies whether he was aware of the discontent and numerous resignations of doctors from the public hospitals and services of Jamaica, petitions of nurses against mismanagement resulting in overwork and under-payment, and the alleged neglect of patients and inability of hospitals to give proper attention to serious cases; and if he would accede to the public demand for an impartial and comprehensive inquiry with a view to remedying the grievances and inefficiency in these services. Colonel STANLEY said he was aware that some dissatisfaction existed in the Jamaica Government Medical Service. He understood that the pay and conditions in that service had been investigated by the local public services committee, and he was awaiting its report with the Governor's recommendations.

Recruitment to Colonial Medical Service

Wing-Commander HULBERT on Jan. 19 asked the Secretary of State for the Colonies what steps were being taken to ensure that an adequate number of doctors were recruited for the Colonial Medical Service during the war. Colonel STANLEY replied that under arrangements made with the Central Medical War Committee, which was the official agency for the supply of doctors, a sufficient number of suitable candidates had hitherto been forthcoming to fill declared vacancies for medical officers in the Colonial Medical Service. A scheme for the building up of a reserve of medical officers was under active consideration.

Insured Persons and the Protection of Practices Scheme

On Jan. 19 Sir E. GRAHAM-LITTLE asked the Minister of Health if he would investigate the case, of which he had been told, in which the County of London Insurance Committee had informed insured persons that, in the absence of their own doctor and of any specified locumtenent, they could not obtain treatment from a National Health Insurance practitioner who was not a member of the Protection of Practices Scheme conducted by the B.M.A., and if he was aware that some insured persons had had to wait some months before getting treatment from the practitioner of their choice and had in the meantime had to pay private fees for medical attention near their homes. Mr. ERNEST BROWN replied: I am informed that insured persons on the lists of absentee practitioners who are participants in the London Protection of Practices Scheme are not directed to go to any particular doctor, but are informed that they can apply to other participating doctors the nearer of whom are named. Doctors who participate in the scheme and are on Service have agreed to accept other participating doctors as their deputies during absence, and the regulations provide that an insured person on the list of a practitioner who has appointed a deputy can transfer to another practitioner only at the end of a quarter and after a prescribed length of notice, except where the former practitioner agrees to an earlier transfer.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* the principal features of the returns of infectious diseases during the week reviewed were the rises in the number of cases of whooping-cough 115, acute pneumonia 155, and dysentery 24, and the falls in the notifications of measles 836, scarlet fever 351, and diphtheria 98. The seasonal rise in mortality from influenza began, and the 65 deaths recorded in the great towns, an increase of 21, constitute the largest total since last March.

A small fall in the incidence of diphtheria and scarlet fever was recorded in most areas of the country, notably in Staffordshire and Yorks West Riding with a drop of 98 and 63 respectively. No marked changes occurred in the local distribution of diphtheria.

The fluctuations in the trend of acute pneumonia were small in most counties, the only differences of note being rises in Warwickshire 43, Yorks West Riding 46, and Durham 31.

The largest rises in the notifications of whooping-cough were Wales 52, Lancashire 50, Cheshire 21, and Durham 20. Whooping-cough is more prevalent in the North than in the South. The cases reported from the combined areas of London, South-Eastern, South-Western, South Midland, and Eastern Counties formed only one-quarter of the total of the country.

There were relatively large variations in the incidence of measles in many counties. The largest drops were in Leicestershire 333, Yorks West Riding 188, Southampton 147, Essex 115, Nottinghamshire 105, and Lancashire 104; and the largest rises were in Derbyshire 187, Sussex 82, Durham 71, Berkshire 65, and Bedfordshire 36.

Three counties were responsible for the higher incidence of dysentery. An outbreak in Essex accounted for 22 cases (Colchester M.B. 16); the notifications in London rose from 14 to 23, involving eleven boroughs, and in Lancashire from 17 to 33 (Blackburn R.D. 25).

In *Scotland* there was a sharp rise in the incidence of infectious diseases, particularly for measles 307, scarlet fever 53, whooping-cough 54, acute primary pneumonia 37, and for diphtheria 19. Notifications of measles rose especially in the burghs of Dundee 107, Aberdeen 93, Greenock 46, and Kirkcaldy 34. Of the 32 cases of dysentery notified, 10 came from the county of Zetland and 11 from the city of Aberdeen. The trend of whooping-cough was mainly affected by the experience of Glasgow, where the notifications went up by 37, while the increase in the number of cases of scarlet fever and diphtheria was fairly general. An outbreak of gastro-enteritis due to food, involving over 100 persons with 2 deaths, occurred in St. Andrews.

In *Eire* the numbers of cases of poliomyelitis have fluctuated round a constant level during the past month. During the week reviewed there were 10 cases from nine areas.

Returns for the Week Ending January 16

The notifications of infectious diseases in England and Wales included: scarlet fever 1,957, whooping-cough 1,504, diphtheria 764, measles 12,323, acute pneumonia 1,194, cerebrospinal fever 96, dysentery 96, paratyphoid 5, typhoid 4. In the great towns there were 89 deaths from influenza.

No. 1

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Jan. 9.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London) (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1943					1942 (Corresponding Week)

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Includes paratyphoid A and B for Northern Ireland.

‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Medical News

Dr. G. M. B. Dobson, F.R.S., will give a discourse on "The Air We Breathe in Town and Country" at the Royal Institution, 21, Albemarle Street, W., on Friday, Feb. 12, at 5 p.m.

The National Institute for the Blind report that 100 civilians in this country are now known to have lost their sight by enemy action. These are additional to blinded members of the fighting and civil defence services. News of the hundredth casualty reached the Institute only a week or two ago, a year after its occurrence. Owing to the delay the wounded person lost the advantage of early specialized training. Hospitals have been asked to report these casualties as soon as possible so that expert help can be given immediately. The patient can then be comforted through the period of shock and may even begin Braille. On discharge from hospital the men and women become guests at the Institute's homes of recovery. Very young victims are received as boarders at the Institute's Sunshine Homes.

Sir Edward Mellanby and Prof. W. W. C. Topley have been appointed to serve on the Colonial Products Research Council, the appointment of which, under the chairmanship of Lord Hankey, was announced on Jan. 18.

In response to inquiries about the new British Standard specification for haemoglobinometers, Haldane type (*Journal*, Jan. 2, p. 14), a circular has been prepared on the "Arrangements for Testing Haemoglobinometers (Haldane), Colour Tubes, Graduated Tubes, and 0.02 ml. One-mark Capillary Pipettes" by the National Physical Laboratory, Teddington, Middlesex, from whom a copy may be obtained on application.

In view of the shortage of doctors, medical officers of local authorities are not to be retired on reaching the age limit if they are fit and willing to continue in their work. The Minister of Health (Circular 2758) reminds local authorities of their powers under the Local Government Superannuation Act, 1937, to extend a doctor's services (with his consent) for one year or under and to repeat this extension if desired They can also re-employ doctors already retired on terms to be mutually agreed, subject to the Minister's approval in appropriate cases.

According to Prof. Gunnar Nystrom of Uppsala more than 500 Swedes die annually from appendicitis alone because they come under medical treatment too late. About 20,000 appendix operations are performed in Sweden every year, and 3,000 patients need a further twelve days' treatment because of delay in treatment.

In a statement published in the Danish press, Dr. Frandsen of the Medical Board is reported to have said that infectious diseases generally are on the increase there. For the period January to November, 1942, there were 56,291 cases of acute diarrhoea, as compared with 2,954 in the corresponding period of 1941. There was also an increase of cases of jaundice, of from 2,586 in 1941 to 9,040 in 1942.

A medical faculty has recently been established at Abo, Finland.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be sent to the Secretary.

TELEPHONE No.—B.M.A. and *B.M.J.*: EUSTON 2111.

TELEGRAPHIC ADDRESSES.—EDITOR, *Aitiology Westcent, London*; SECRETARY, *Medisecra Westcent, London.*

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

QUERIES AND ANSWERS

Income Tax

Income Remaining Abroad

M. is now permanently resident in this country but has investments in Australia. Is M. liable to British income tax on dividends which are not remitted to this country?

⁂ Yes. There is, of course, the statutory measure of relief in respect of the tax paid in Australia.

Marriage—Effect on Allowances

"S. P." has a resident appointment at £200 a year and was married last November. How is her liability affected?

⁂ In the current financial year, 1942–3, "S. P." will be entitled to exemption up to the date of marriage, and for the period from her marriage to April 5, 1943, any liability will be covered by the £80 allowance to married women earning income, and the ordinary 1/10th earned income allowance. Her husband will be entitled to the married man's allowance of £140. In the next financial year, 1943–4, "S. P." will be liable, subject to deduction of the £80 and the 1/10th earned income allowance.

LETTERS, NOTES, ETC.

Scabies

Dr. HAROLD E. WATKINS (Newton-le-Willows, Lancs) writes: An ointment, called here "ung. pro scabies," was brought to my notice in 1921, and I used it until I retired from general practice in 1936. It is the prescription of a Danish doctor, and was prepared according to the Danish Marcussen formula. With one exception, one application only was sufficient to effect a complete cure; in this one case a second application did cure completely. I have never known the ointment to cause any signs of skin complications. Reference is made to this preparation in the *Lancet*, 1920, **2**, 1251; *Wien. klin. Wschr.*, 1921, **34**, 94; *Medical Annual*, 1922, p. 376; *British Medical Journal*, 1930, **1**, 1080; and the formula was adopted by the *B.P.C.* in 1934 under the title "Ung. potass. polysulphid." The instructions for its application are: "The patient receives an ordinary cleansing bath, wipes himself thoroughly, and then rubs the whole body, except the head, with the ointment. After a quarter of an hour in the upright position he goes to bed, and 24 hours later has a second cleansing bath and puts on fresh and disinfected clothing." All body and bed clothing must be disinfected, as the eggs hatch there and start the process all over again. The eggs get into the clothes by the scratching. The formula of the ointment is—as stated in the *B.P.C.*: Potassium hydroxide 1/2 oz., sulphur sub. 1/2 oz., paraffin. molle 394 grains, wool fat 394 grains, zinc sulphate 49 grains, sodium hydroxide 14 grains, distilled water 302 minims, benzaldehyde 10 minims, liquid paraffin to 4 oz. I am indebted to Messrs. James Woolley Sons and Co. Ltd. of Victoria Bridge, Manchester, 3, for the above formula. I have always obtained the ointment from this firm, and have no doubt that they will be able to supply any doctor on application.

Treatment of Migraine

Dr. NEVIL LEYTON (London) writes: I have read Mr. G. F. Rowbotham's article (Dec. 12, p. 685) on the pain pathways in migraine with interest. And his suggestion for treatment of headaches of this type where there is no organic lesion is likely to bring relief to many. Having myself recorded the successful treatment of migraine and neurasthenia both in the female *and* in the male by the use of A.P.L. hormone (*Lancet*, 1942, **1**, 488) I think that it would be well worth trying this drug in cases of migrainous headache in post-concussional cases. The treatment is so simple and the relief, if relief there is to be, so noticeable early in the treatment, that it might save surgical intervention in many patients.

Sacro-iliac Strain

Dr. K. WILSON JAMES (Jamaica) writes: The sacro-iliac joint is of the diarthrodial variety, possessing a small synovial cavity. The joint is almost immovable, but owing to the heavy musculature surrounding the pelvis and the constant stress to which that structure is subject, sacro-iliac strain, when it occurs, can be very resistant to treatment. Attendant upon the strain, pain sets up muscular spasm and, associated with it, a certain amount of vasoconstriction. This leads to a diminished blood supply to the injured structures and delay in healing. Thus a vicious circle is established with a tendency for the condition to become chronic and incapacitating. This vicious circle can often be broken, particularly in the early stages, by injection of 1/2% novocain into the surrounding painful ligaments. These ligaments—the posterior and oblique sacro-iliac and the upper fibres of the sacro-sciatic—are easily accessible for infiltration with a local anaesthetic. Occasionally in severe cases a longer-acting, oily anaesthetic (proctocaine) can be used, and injections can be repeated. Results are often dramatic. Following the injection the patient, who should wear an elastic girdle, which is slightly restrictive and also gives some support, should be allowed up from the start except in very severe cases, and moderate exercise should be permitted. This procedure, although simple and not spectacular, and used either alone or as a supplement to the other recognized forms of treatment usually employed, has a definite place in the treatment of sacro-iliac strain.

THE TREATMENT OF CEREBRAL CONTUSION*

BY

LAMBERT ROGERS, M.Sc., F.R.C.S.

Surgeon Captain, R.N.V.R.

Professor of Surgery, University of Wales; Surgical Consultant, R.N. and E.M.S.

Cases of cerebral contusion following so-called "closed" head injuries are usually admitted to beds in the general surgical wards of a hospital, and two tendencies may be noticed in regard to them: first, like fracture cases in the same wards, they are not infrequently regarded rather as necessary evils and relegated to the care of the house-surgeon; secondly, treatment is usually of a symptomatic character—e.g., for restlessness—without due consideration for the complex pathological processes which result from the injury to the brain and are involved in its recovery. It is not surprising, therefore, to find these cases either just left recumbent, or else subjected to various methods of treatment, which for the most part may be described as of an expectant character, consisting merely of rest in bed and efforts to palliate complications as they appear.

What, then, should we do for a patient rendered unconscious by a severe head injury and who may or may not present an obvious lesion such as a scalp wound, for which local treatment is required? Although such cases are of frequent occurrence it is true to say of them that, first because of the extreme variability in the severity of head injuries and of their effects, rarely, if ever, do any two have identical cerebral lesions; and, secondly, even after a prolonged period of unconsciousness some of them make remarkable recoveries, even if given little or no treatment at all—e.g., just left to lie on a bunk, as happened in sailing-ships in olden days. Obvious difficulties, therefore, are encountered in testing the efficacy of any particular form of treatment for such cases. The fact remains, however, that many patients who recover from the immediate effects of closed head injuries do present sequelae in the form of the so-called post-concussional state. We may accordingly ask whether it is not possible to lessen the incidence or altogether avoid this post-concussional state by adopting prophylactic measures in the form of early treatment. It is my belief that it *is* possible, and the object of this paper is to record experiences with a method of treatment which I contend is indicated on theoretical, experimental, and clinical grounds, and which appears to promote the recovery of these patients, with a singular freedom from complications or after-effects.

If, following a particular form of treatment, convalescence is smoother than it is otherwise known to be, and if there is a consistent absence of sequelae known to occur from time to time in cases not so treated, it is suggested that we have a strong argument in favour of that treatment—provided always, of course, that the treatment itself does not add to the mortality of the condition.

Testing the Value of Treatment

What methods have we for testing the value of a particular form of treatment? The answer is not as simple as it might seem to be at first sight. It would appear that all we had to do was carry out direct experiment—i.e., test the remedy; but it has already been pointed out that many patients recover whether a particular form of treatment is given or not, and they may do so even despite it. Next, since no two cases of head injury—which term implies a complex and variable pathology—are quite alike, it is difficult to obtain controls by which to effect anything like exact comparison. Lastly, while a certain amount of information is to be gained from animal experiments, there are obvious fallacies in transferring the results of such experiments to man or in attempting to draw conclusions from clinical observations made on animals. To test the evidence, therefore, the most scientific course will be to adopt a combination of methods such as the following:

(i) To examine the argument for the particular remedy by careful consideration of the premisses on which it is based and the conclusions to be derived therefrom.

(ii) To review the experimental evidence bearing on the argument.

(iii) To examine the results of a series of treated cases, followed over some years, particularly noting the incidence of complications known to occur from time to time with other methods of treatment.

(iv) To review a few cases in some detail while, so far as possible, making allowance for the qualifications already mentioned.

It is first necessary to indicate the type of treatment. Briefly, this consists of continued gentle dehydration, instituted with the object of withdrawing cerebrospinal fluid from the intra cranial cavity and so providing potential space into which brain-swelling can take place, thereby avoiding compression of its blood vessels.

I. The Argument

The argument in favour of this form of treatment is briefly the following: Bruised tissue, whether that comprising the brain or any other organ or structure, must be permitted to swell if it is to recover completely. If by confinement within a limited space swelling is prevented there must be a reduction in blood supply owing to the compression of the vessels supplying the damaged tissue, and this reduction is detrimental to complete recovery.

While to-day the Monroe-Kellie doctrine may not be wholly acceptable in the form in which it was originally propounded, it is probably true to say that with certain reservations the data on which it is founded are true and that in general it holds good. There is a relatively fixed total volume of the cranial contents, but with a capacity for change in any one of the three chief elements comprising it—viz., the brain itself, the circulating blood, and the cerebrospinal fluid. The most practical method of providing for swelling of the bruised brain is to reduce the amount of the cerebrospinal fluid within the skull. This may be conveniently done by dehydration.

If tissue-swelling is allowed to take place after injury the subsequent recovery of the tissue is striking; if, however, swelling is restricted or prevented altogether, a varying degree of permanent damage follows. This important principle of pathology is exemplified when an organ readily capable of expansion—like the kidney—is compared in its reaction to injury with an organ restricted by its capsule from expanding—like the testis. The renal capsule is thin and readily distensible; the testicular capsule (tunica albuginea) is tough, fibrous, and comparatively inelastic. The bruised kidney swells, recovers, and functions normally; the bruised testis cannot swell, and subsequently atrophies. The cerebral envelopes are even more rigid than the tunica albuginea, and the only way in which some variation can be given to their limits of constriction, other than by craniotomy (with its attendant risks and disadvantages), is by reducing the volume of the cerebrospinal fluid surrounding the brain, the fluid itself being incompressible. As Wilfred Trotter (1929) has pointed out, a simple bruise, of no ultimate importance to an organ with a yielding capsule, is a serious matter with the brain, which must be allowed to swell if its circulation is not to be materially interfered with. If this swelling, which is the normal reaction to injury, is restricted, the blood supply to the bruised region is diminished, and the ensuing ischaemia may well result in cortical atrophy with associated ventricular distension or become manifest by symptoms such as those which comprise the post-concussional state. This post-concussional state may conceivably represent incompletely resolved cerebral contusion or subsequent atrophy consequent upon failure to provide for brain-swelling following injury.

---

* Based on a lecture delivered at the Royal Naval Hospital, Plymouth, Jan. 7, 1943.

Brain-swelling.—In the case of the brain, injury produces swelling very readily and to an extreme degree. Thus, Dandy (1941) writes: "Trauma that would cause no concern to other hardier tissue produces severe swelling of the brain." Some idea of the extent of this swelling and the rapidity with which it occurs can be gathered from cases of cerebral tumour which have undergone operative treatment. In this connexion the same author writes: "The large cavity created by the tumour's removal may be entirely obliterated in less than half an hour, and with no gross haemorrhage."

One of the arguments advanced against the routine use of dehydration to permit brain-swelling to occur in cases of closed head injuries is that from time to time the pressure of the cerebrospinal fluid in the lumbar pond of patients unconscious as a result of a severe head injury has been found to be low. This, however, does not invalidate the thesis or contraindicate dehydration—first, because experimentally (White *et al.*, 1942) no correlation has been found to exist between cerebrospinal fluid pressures and the degree of cerebral swelling (e.g., as produced during anoxia); and, secondly, because variations in the pressure of the fluid in the lumbar pond take place so frequently that an isolated observation that at one particular time it is low is probably of little significance. Finally, it is reasonable to assume that such pressure differences as occur during brain-swelling are chiefly of a local character and may require intracellular observations to detect them; or, as White (1942) has recently suggested, in head injuries there is often concomitant anoxia of the brain due to depression of the respiratory centre, and this anoxia may considerably reduce the secretory activity of the choroid plexus.

Still further evidence that the findings at lumbar puncture are not necessarily an indication of the intracranial fluid state has been found at operation; thus Bathe Rawling (1918) wrote in connexion with subtemporal decompression which he was at that time performing for cases of suspected cerebral oedema: "In one of my last cases four punctures carried out immediately previous to operation showed a great diminution in the amount of cerebrospinal fluid; and, in the operation performed immediately afterwards, the opening of the dura showed a most typical condition of cerebral oedema with very great excess of fluid."

II. Experimental Evidence

Experimentally it should be possible to ascertain whether brain-swelling takes place following head injury: White (1942) has found a very constant swelling of the brain of cats, even after the animals have had mild concussion—e.g., the brain, instead of being 10 to 11% smaller than the intracranial chamber, was found to be only 7 to 8% smaller. Surgeons (including myself) who have operated on cases of closed head injury within the first few hours have commented on the swollen condition of the brain. Furthermore, it is a widely held view, and probably true, that when a compound fracture with its immediate decompressive effect has occurred convalescence is easier and freer from complications than when a comparable type of injury has produced cerebral contusion alone.

Turning next to the other side of the problem, Weed and McKibben (1919) constantly found histological changes in the brains of animals given intravenous injections of hypertonic or hypotonic solutions if by keeping the skull closed the brain volume was not allowed to alter. On the contrary, however, when the brain volume was allowed to alter by opening the skull with a trephine these histological changes did not take place.

Provision for Brain-swelling.—If brain-swelling which is the normal reaction to injury is allowed to take place the blood supply remains relatively unimpaired and resolution and recovery are complete. If the swelling is restricted local blood supply is impeded and may be followed by changes which are evident clinically as the "post-concussional state." Theoretically, provision may be made for brain-swelling by performing craniotomy or by withdrawing the incompressible cerebrospinal fluid from the skull; for, as Dandy (1933) has pointed out, "space compensation is the principal function of the cerebrospinal fluid." This fluid-withdrawal may be either by lumbar punctures or by dehydration, or it may be effected by a combination of both methods. In practice it has been found that craniotomy is unnecessary and undesirable and that dehydration is the procedure of choice, probably because this is a continuous and gentle process, whereas repeated lumbar punctures result in a rapid to-and-fro swing of cerebrospinal fluid production and thus are only occasionally employed to augment dehydration or for diagnostic reasons.

Dehydration by Magnesium Sulphate.—The question arises whether it is possible by any simple measures to produce the continued gentle dehydration previously advocated, and the reply is that this can be effected by instillations of magnesium sulphate into the rectum at regular intervals. Cushing and Foley (1920) showed that 20 to 30 c.cm. of a saturated solution of sodium chloride introduced into the duodenum or the rectum of the cat produced a maximal fall of cerebrospinal fluid pressure precisely comparable to that which occurred when the solution was given intravenously. They pointed out, moreover, that when the salt is given by the alimentary route the intracranial changes which are produced are not only not attended by disturbances of pulse, respiration, or blood pressure, but that possibly, also, alteration of the cellular elements of the blood is avoided. Temple Fay (1924) found that magnesium sulphate instilled into the rectum had advantages over sodium chloride in causing less discomfort and being almost twice as efficient in its effects on the cerebrospinal fluid. Being non-dialysable and therefore not absorbed into the blood stream, magnesium sulphate does not produce a secondary wave of tissue oedema with an increase in intracranial pressure as does the sodium salt. Writing of the rectal use of magnesium sulphate in the University Hospital in Philadelphia, he states: "The beneficial use of this salt in cranial injuries has been well established in this clinic." This has also been our experience at Cardiff. Its use in the treatment of cerebral oedema has also been endorsed by Donald Munro (1938) and others.

The details of treatment are briefly as follows: (1) The patient is propped up in bed with the head raised to reduce intracranial venous congestion, and for the same reason it is necessary to make sure there is no constriction of the neck veins by tight pyjama collars or other garments. (2) Retention enemas of 6 oz. of 30% magnesium sulphate solution in water are given every six hours. These must be very gently and slowly administered so as to be retained. (3) Fluid intake by mouth is restricted and a certain degree of thirst is a criterion of effective dehydration.

III. Examination of Results

In 1929* this practice was begun in the surgical unit at the Cardiff Royal Infirmary, and has consistently been followed since in all cases of head injury severe enough to be admitted (Lambert Rogers, 1935, 1937, 1938a, 1938b). The majority of these patients were in a state of profound or prolonged unconsciousness. In the years between 1929 and 1940 550 cases were treated. Fractures of the skull were detected in 133 of these, but there is reason to believe that many others had basal fractures not revealed by *x*-ray examination. Of these patients 25 died, the majority soon after admission.

An absence of both immediate and late complications has been noticed. Traumatic delirium (cerebral irritation) was infrequent, and when it did occur was only of a mild character. The absence of the noisy, shouting, restless type of patient with head injury, previously so often seen, was a welcome change which has often been commented upon by those taking part in the dehydration treatment. Furthermore, if focal signs arose in the course of treatment these were considered to indicate craniotomy, and were found at operation to be caused by blood-clot and not oedema, which in some cases previous to the dehydration regime had been revealed when these cases were operated upon because of the onset of focal signs. Lastly, although a follow-up clinic is maintained in connexion with the surgical unit, not one of these 525 cases has required readmission because of the so-called post-concussional state or sequelae of any kind. It is tempting to doubt, therefore, whether there is such a condition as the post-concussional state if brain-swelling is permitted to take place at the time of injury, and whether in fact this state, as has already been suggested, does not represent incomplete resolution the result of failure to institute effective initial treatment. It is perhaps pertinent to remark that during the period under consideration cases of so-called post-concussional state were admitted from other clinics where dehydration had not been carried out.

---

* The idea followed Wilfred Trotter's teaching of the pathology of brain injury, and I had thought we were the first to institute the practice, but have since read that this treatment was in operation in 1921 on the neurosurgical service of the late Dr. Charles H. Frazier (Temple Fay, 1935).

IV. Review of Some Cases

The following details of a few cases exemplify the result of this treatment.

Case 1 : Fracture of base of middle fossa extending into right parieto-occipital region of vault. Cerebral contusion and laceration. Spastic paraplegia, right brachial monoplegia, left facial palsy, cyanosis, coma three weeks, cerebral irritation, bilateral suppurative otitis. Dehydration 15 weeks. Recovery complete.—A physician aged 53 was admitted after a motor accident, a fast-travelling lorry having collided with the side of the taxi-cab in the back seat of which he was sitting. On admission he was cyanosed and in profound coma; respirations were deep and noisy; he was bleeding from both ears and nostrils. There was a superficial scalp wound on the forehead and a haematoma over the occiput. There was a slight right facial palsy; the right arm was spastic, the left flaccid; there was spasticity of both legs, and the plantar reflexes were extensor. Death appeared to be imminent. He was propped up and dehydration begun. Lumbar puncture two days after admission showed a pressure of only 100 mm. water and red opalescent fluid; 20 c.cm. were withdrawn, and this was repeated 2 days later. Systolic blood pressure, 164 mm. Hg. Radiographs showed a "vertical fissure in the right occipito-parietal region." At this time he was groaning unceasingly, and was rather restless and still profoundly unconscious; the right arm was paralysed, but he was moving his left arm and both legs. The facial palsy had increased slightly. Three weeks later he developed suppurative otitis media in both ears. He was irrational but recovering consciousness, though unable to recognize an old friend. Later still the plantar reflexes became flexor; he was less excitable and had no headache, but complained of tingling in his right arm. Blood pressure, 130 mm. Hg. Dehydration was continued for a period of 15 weeks. Recovery was complete, and he returned to active consulting practice. For the seven years which have since elapsed he has worked consistently, is apparently normal in all respects, and is at present working harder than ever.

Case 2 : Linear closed fracture. Cerebral contusion, coma, delirium, right monoplegia soon proceeding to hemiplegia, middle meningeal haemorrhage. Bone flap; removal of 83 g. of extradural blood-clot. Dehydration 1 week. Recovery complete.—A farmer aged 33 was involved in a brawl in a local inn and hit with a ploughshare on the left side of his head. He was a big muscular man, over 6 ft. tall, and on admission was unconscious and very restless. Pupils reacted very sluggishly to light and both plantar reflexes were extensor. Dehydration was begun on admission. He remained unconscious for three days, but gradually became more docile as he was dehydrated. He then developed a right monoplegia which soon progressed to a hemiplegia. The systolic blood pressure was 90 mm. Hg. A linear fracture traversed the left parietal and squamous temporal bones. A left parietal bone flap was turned down and 83 g. of extradural blood-clot removed. He made a complete recovery, power returning first in the leg and then in the arm.

Case 3 : Closed head injury—probable basal fracture—unconscious 48 hours. No dehydration; intense headache, bradycardia; semi-conscious and very restless when seen. Dehydration 14 days. Rapid improvement and recovery.—An Army officer aged 35 fell from a lorry, struck his head, and was admitted unconscious to a cottage hospital. He was kept lying in bed for five days, and when then seen was semi-conscious, restless, vomiting, and complaining of intense headache. The pulse rate was 56; the cerebrospinal fluid was intimately mixed with blood. He was propped up and dehydration begun. The change was rapid, his headache being relieved, the vomiting ceasing, and restlessness subsiding. The matron of the cottage hospital volunteered the remark that the magnesium sulphate instillations relieved his headache. He was dehydrated for a fortnight, and was discharged symptom-free.

Case 4: Closed fracture, right parietal, following fall of 20 ft. Unconscious 2 hours, subsequently drowsy. Dehydration 5 days. Recovery complete.—A dockyard labourer aged 22 had an epileptic fit and fell from some staging about 20 ft. He was admitted to hospital, remained unconscious two hours, and was subsequently drowsy. He remembered feeling he was going to have a fit and then later finding himself in hospital. He was dehydrated for five days. The medical officer reported that he became less drowsy after the dehydration and made a complete recovery.

Case 5 : Closed fissured fracture, left parietal, following fall from lorry. Unconscious for few minutes. Wound of pinna. Dehydration 3 days. Recovery complete.—A marine aged 35 fell out of the back of a lorry and was unconscious for a few minutes only. On admission to hospital he had headache, was drowsy, and desired only to sleep; his cerebration was slow. He was dehydrated for 3 days, and the medical officer noted: "Patient benefited from dehydration. It relieved headache and he became brighter."

Case 6 : ? Fracture in parieto-occipital region. Closed head injury. Fall off back of lorry; unconscious 15 hours. Intense headache. Dehydration 7 days. Recovery complete.—A pensioner yeoman of signals aged 42 fell off the back of a lorry and was admitted unconscious. He remained so for 15 hours, and, although when he regained consciousness he was mentally alert, he was depressed and had intense headache. Medical officer noted: "Patient obtained benefit from dehydration. Headaches were relieved."

Case 7: Closed injury. Patient found lying unconscious beside bicycle in road. Abrasions of face, hands, and leg. Dehydration 18 days. Recovery complete.—An A.T.S. officer aged 30 was admitted unconscious to hospital, having been found in the road beside her bicycle. She remained unconscious for 6 days and was then unresponsive and drowsy, and complained of intense headache. The optic disks showed slight papilloedema; and the pulse was consistently below 60. The electro-encephalogram showed no abnormality in any area, but she was not made to overbreathe. When she was first seen either brain-swelling or a subdural haematoma was suspected. Remarkable changes followed dehydration. Once this was effectively instituted she made an uninterrupted and rapid recovery, and was discharged symptom-free.

Case 8 : Closed injury following fall off lorry; semi-conscious, traumatic delirium, hemiplegia. Dehydration 3 weeks. Recovery.—A soldier aged 25, fell out of a lorry on to the road and was admitted to a local hospital in a semi-conscious condition. He became very restless and irritable, and was noticed to have a hemiplegia. When seen 48 hours afterwards he was still only semi-conscious, very restless, irrational, irritable, and hemiplegic. The right plantar reflex was extensor, the pulse between 50 and 60. Lumbar puncture showed blood intimately mixed with the cerebrospinal fluid. Following dehydration he made a rapid recovery, his symptoms disappearing from the time of its institution.

Not once, but many times recently, I have had the experience of finding a young Service patient with a head injury lying flat in bed, unconscious, irritable, and restless, and within a few hours of propping him up, doing a lumbar puncture, and beginning dehydration therapy, seen him become a conscious rational being once more. I attribute such changes to the recognition of the importance of brain-swelling and the provision thus made for it.

While there have been difficulties in getting this treatment accepted as a routine measure in this country and few British neurosurgeons, with the exception of Wylie McKissock (1942), have openly supported it, there have not been lacking elsewhere those who have upheld the claims made for it. In the United States Foster Kennedy and Wortis (1932) have advocated dehydration treatment, and Temple Fay (1937) claims not only a reduction in mortality of somewhere about 25% in head injury cases so treated but that there is a remarkable improvement from the standpoint of subsequent economical and social adjustments. He writes: "If its [the brain's] tissue can be maintained alive during the crisis, a prompt return of function will follow to a far greater degree than has formerly been recognized. . . . What surgeon would permit a patient with a bed-sore to continue pressure on the area and expect the devitalized anaemic tissue to recover its function? Yet many . . . permit a brain to become involved in a relentless hydraulic compression, squeezing the blood out of this vital and important tissue." On the Continent, Decker (1938) of Lausanne has upheld its value, claiming a lowering of mortality and improvement in results since its adoption, and there have been others who from time to time have spoken or written in favour of it.

But for the most part these have been "voices crying in the wilderness." Anything like routine appears to be abhorrent to some surgeons, yet the reaction to injury must at least be always in the same direction, and if bruised brain always reacts by swelling, treatment surely should always be directed to providing for the swelling to take place.

Conclusion

To sum up, then, we may inquire whether the Monroe-Kellie doctrine does hold in regard to the reaction of the bruised brain to injury. Is the encapsulation of the brain by cranium, meninges, and cerebrospinal fluid of a comparatively rigid and inelastic character like the tunica albuginea of the testis, as has already been suggested, or does it by some physiological mechanism readily accommodate to cerebral swelling as does the thin elastic renal capsule to swelling of the bruised kidney? If, as it seems to me, the encapsulation behaves in a comparatively rigid and relatively inelastic manner, there can be no questioning the desirability of directing our treatment of the bruised brain towards an attempt to render the cerebral encapsulation more accommodating and thus to maintain the blood supply to the contused area by permitting it to swell in response to the law of its reaction to injury. It is further contended that the best method of doing this is by continued gentle dehydration to facilitate brain-swelling and so prevent the reduction in the blood supply to the damaged areas of the contused brain.

There is some reason to think that our forefathers may have had some inkling of the benefits of dehydration. Ambroise Paré over 300 years ago advocated restriction of fluids, purgation, and sweating for cases of head injury (Turnbull, 1939); and the prescribing of calomel and salts and otherwise purging of patients with fracture of the base of the skull, which was common practice early in this century, was probably introduced quite empirically, but was nevertheless essentially sound.

Perhaps in addition to the striking clinical improvement which is so often observed as soon as this treatment is instituted, the absence of sequelae in a long series of cases is the best criterion on which to base its claims. It is simple—so simple that it tends to be neglected or perhaps rather scornfully regarded, as Naaman was inclined to treat the advice of Elisha (ii Kings v). The Syrian captain was angered and disappointed that the prophet had not come down and performed some miracle. In these cases of severe closed head injury with profound unconsciousness it would be so much more dramatic to perform wide decompressive craniotomy, but the simpler treatment is so effective that, like bathing in the Jordan, it suffices. To those who are still not convinced by the arguments here put forward, the figures presented, or the cases instanced, one may quote what was once graphically said of some numerical evidence: "An emaciated child suffering from hunger is a more impressive sight than any number of mortality statistics." A few cases treated by this method will prove more convincing than any theoretical considerations.

Summary

Prolonged unconsciousness following a severe head injury, particularly when blood is intimately mixed with the cerebrospinal fluid, would indicate that the brain has been bruised or torn. Evidence is presented that the brain reacts to such injury by attempting to increase its volume.

No two head injuries are exactly comparable, and it is well known that remarkable and complete recoveries are often made from extensive injuries to the skull and brain. It is difficult, therefore, to assess the value of any particular type of treatment. The absence of sequelae following the consistent application of any particular form of treatment, however, may be urged in its favour.

Dehydration is a method of permitting brain-swelling to take place after injury, and the evidence in favour of its application is here examined. It should be effected by rectal magnesium sulphate and not by intravenous methods, which probably produce undesirable reactions.

Smoothness of convalescence and an absence of sequelae—e.g., the so-called post-concussional state—have been noticed after treatment of a large series of cases by continued gentle dehydration.

It is suggested that the post-concussional state may, in many cases at least, be the result of failure to introduce effective treatment in the early stages and represent a condition of unresolved contusion, it being maintained that resolution takes place readily and completely if the requisite condition for reparation is provided. It is suggested that this is the provision of space so that brain-swelling can occur and is not restricted by the cerebrospinal envelopes, with consequent impairment of the cerebral blood supply. Provision for such swelling is made by sustained dehydration, which reduces the incompressible water-content of the skull.

THE NATURE OF THE RHEUMATIC CHILD

BY

DOUGLAS HUBBLE, M.D.Lond.

Assistant Physician to the Derbyshire Royal Infirmary; Physician to the Derbyshire Hospital for Sick Children

(Concluded from p. 125)

Aetiological Factors in the Rheumatic State

It should be generally conceded that statistical inquiry has a more limited value in such a disorder as the rheumatism of childhood than it has in many other diseases. Diagnosis is more than usually difficult, so that the outlook, the experience, and the bias of the individual clinician have to be assessed. The conclusions, too, are valid only for the time and place in which they are made. This may be true in some degree of all statistical investigations, but it is most true of diseases that are disorders of personality and environment. So it should surprise no one that careful investigations by experienced observers at different times and in different places arrive at contrary conclusions with regard to the aetiological factors of rheumatism. The influences of climate, of heredity, of poverty and its accompaniments, are still keenly debated. It may be said of climate that its influence is equivocal; the disease is certainly not limited to northern latitudes and temperate climates as was once taught (Swift, 1940; Fernando, 1939), and it seems probable that the higher incidence of rheumatism in cold than in hot climates depends on the increased liability to respiratory infections in these areas. In England the geographic distribution of the disease cannot be shown to depend on climatic factors (Morris and Titmuss, 1942).

It is generally admitted that the disease shows a well-marked familial incidence, but in Great Britain most observers agree that this depends more on exposure to similar environmental stresses than on an inherited quality. In America, observers are inclined to attach more importance to the influence of heredity, but there are many facts (some of which are dealt with below) which suggest that the heritable factor cannot be of dominant importance. There are, however, three factors—age, social grouping, and the haemolytic streptococcus—about which opinion may be more dogmatically stated. Of these factors it may be said that unless an individual is between the ages of 3 and 15 it is uncommon for him to develop the disorder for the first time; that if he belongs to the wealthier classes he will with great probability escape it altogether, and that, if he does develop it, then at some phase of the illness, but not always at the start, the presence of the haemolytic streptococcus can be demonstrated. These factors deserve more attention here.

Age

There is no other infection which, while conferring no immunity, limits itself so accurately to an age group. This fact alone should be sufficient to characterize it not as a disease caused by an invader but rather as a disease conditioned by the host. This age group is paramount. Why?

The peculiarity of this age group is growth, and yet children grow more quickly in the cradle and continue to grow after puberty, so that physical growth does not suggest a solution. The fact that chorea is limited to this same age group confirms those who believe that rheumatism is an infection in their belief that chorea too is caused by the rheumatic invader. On the other hand, those who believe that chorea is a profound nervous instability, proved to follow psychic stress, will be encouraged by this age-grouping to look for a comparable nervous instability in non-choreic rheumatism. Physical growth is a silent progress to predestined stature (always granted a guaranteed nutrition). The growth of personality is a pilgrimage attended with difficulty and beset by dangers. The rheumatic age embraces the years when the child steps down from its cot into the family, and then out into the world—the years of integration and adjustment. I take it to be no coincidence that these are the years of growing pains, of chorea, and of rheumatic carditis.

Social Grouping

There is general agreement on both sides of the Atlantic that child rheumatism is much more frequent in the poorer classes. There are no comparable groups of statistics for the children of the poor and the rich; but Still (1927) found it to be nearly 20 times more common among his hospital out-patients than among the children of the same age group in his consulting practice. Glover (1930) suggests that it is 30 times more common among the poor. This is not to suggest that it is an unknown disease among the well-to-do. American writers often emphasize this (Kaiser, 1934), and epidemics among relatively closed communities of wealthier children in this country have been described (Bradley, 1932).

Large-scale investigations in Great Britain made by the Medical Research Council (1927) have established the fact that the incidence of rheumatism is not in direct relation to the degree of poverty.

> "Indeed," writes Still, "if the hospital patients are divided into three classes according to the degree of poverty, the poorest of these three, the very poor and destitute, show a lower incidence of rheumatism than the other two. It would seem, therefore, that if poverty is a factor in the incidence of rheumatism it must be on account of some condition or conditions associated therewith which are not equally present in all degrees of poverty."

Although this conclusion has been contested by some, there should be no doubt that it was valid for the time and place at which the "investigations" quoted were made. Morris and Titmuss (1942) have questioned it on the grounds that the mortality rates show a steep rise in deaths from heart disease coincident with decline in social status right through to the lowest social group. This criticism carries an obvious fallacy, since it might be expected that once the extremely poor child had become rheumatic its chance of survival was less than that of its wealthier brethren; mortality rates from heart disease in social groups cannot be accepted as an adequate reflex of the incidence of rheumatic disease in those groups.

Findlay defines this social status more closely: "It would seem, however, that it is not the very poorest but rather, if one may so express it, the better-class poor families that have been better off and have fallen on evil days." The Medical Research Council report thus described these families, which it labels "Group B," Group A being the less poor and Group C the very poor: "They are normal households, for the most part with adequate furniture, but have no margin for anything beyond the bare necessities of life, and are liable to periods of deprivations should loss of work occur. They have few outside interests, and are mainly occupied with the struggle to make ends meet."

No observer has suggested that the mental and nervous stresses of poverty on children may be as important as the physical. It needs little imagination to see that the nervous stresses of poverty will be greater in Group B than in Group A or C, greater than in the less poor and in the more poor—that is, in the family which has known failure and is preoccupied with the fear of falling again, with its struggle to keep up appearances, with its avoidance of social life, with its emphasis on hard work as a prelude to success, and with the distortion of its emotional life by fear and insecurity: this is the domestic background to Group B families. Is it fantastic to see in this environment one of the breeding-grounds of child rheumatism? In which class should we expect to find that education imposes a greater nervous strain? Although this factor of nervous instability may explain the higher incidence of rheumatism at this particular economic level of poverty, the general association of rheumatism with poverty at all levels probably depends, as a host of observers have assumed, on the physical accompaniments of poverty, poor clothing, bad and damp housing, malnutrition, and overcrowding. While most of these factors operate by reducing the resistance to infection, others such as overcrowding presumably act by increasing the number and virulence of nasopharyngeal infections.

Strong evidence against the importance of a heritable factor was provided by the M.R.C. report. Evidence was collected from the Poor Law residential schools, and it was found that children living in these institutions much less frequently developed the rheumatic state than children of the same class living at home. At two of these schools, in 22 and 18 years respectively, there had been only five cases of chorea and five cases of acute rheumatism out of more than 6,000 children who had passed through them. It may be estimated that 200 of these children would during that time have developed rheumatism or chorea had they remained in their own homes. Rheumatism in childhood is a disorder based on environment, although a predisposition may be inherited.

The Haemolytic Streptococcus

There is in any rheumatic child a phase in the development of the rheumatic state which is intimately associated with infection, and this infection can usually be shown to be associated with the haemolytic streptococcus. Sometimes, when the rheumatic state develops three weeks after an acute tonsillitis, the "invader" seems to have sufficient power by its own strength and numbers to overwhelm the body defences; sometimes, as in the subacute rheumatic state and in chorea, there has been preliminary "fifth column activity" in the nervous system which has weakened the capacity for resistance to the invader. There is no means, except by clinical approach, of assessing the relative importance of these various factors in any individual or of estimating their aetiological importance in various peoples. It is certain that these factors will vary in importance with race, with country, with social grouping, and with sex.

The view that emotional disorder may lower the resistance to infections may be difficult for some minds to accept, but it is in fact a commonplace of paediatrics. Cameron (1929) writes of the nervous child:

> "Lowering of resistance to infection of all sorts is clearly incurred. The frequent illnesses of the delicate only child have a real existence. They are not to be explained as imaginary ills due to the too great anxiety of the mother. The timid excitable child, with his faulty physique and wrong posture, not only catches every infection possible but responds to each with a violence peculiarly his own."

This review of the aetiological factors in the rheumatic state suggests that the nearly absolute limitation of that condition to an age group and its common association with poverty do not refute the theory that nervous instability in the child is part of the rheumatic diathesis, nor does the recognized association with infection in some of its phases controvert such a theory.

What Manner of Child is This?

Less than 10% of the children entering the rheumatic state do so by way of subacute rheumatism, and in my own cases these children have more often shown evidence of continued nervous instability than of infection. More than 25% of the children entering the rheumatic state do so by way of chorea, and it is suggested that this condition also is evidence not of infection but of profound nervous instability. If these aetiological assumptions are accepted then a third of the children who develop rheumatic carditis show evidence of preceding nervous instability. If this nervous instability is a component of the rheumatic state can it be shown to be present in other children with active rheumatism who have not suffered either from subacute rheumatism or from chorea?

I attempted to find evidence of this nervous instability in 21 consecutive cases of active rheumatism, none of these patients having suffered from chorea or from anything resembling subacute rheumatism. I did not regard the history as displaying nervous instability unless the child showed some disorder of physical process such as insomnia, somnambulism, or night terror; anorexia, diarrhoea, or acquired enuresis; fatigue, fidgetiness, or habit-spasm; pains, whether of head, abdomen, or limbs—and in addition some evidence in the mother's story of emotional disorder or environmental difficulty.

The results of this inquiry were disappointing—only three of the 21 children showed evidence of nervous instability when judged by this exacting standard. The parents of two other children, however, told a story of environmental stress that seemed so closely related to the onset of the rheumatic infection as to provide an aetiological factor. Neither of these two children showed any previous psychological abnormality. One other point of importance emerged. The parents of 16 of these children described them as unusually excitable —such excitability, for the most part, going back to the "toddler" age. It was notable, too, that eight of these mothers used the expression "inwardly excitable." Of these 21 children 12 were described by their mothers as unusually timid or shy. It was as a rule easy to detect evidence of excitability or timidity in these children. This inquiry disappointed me until a year ago, when I read an article by Neustatter (1937), which began with a remark made by Prof. H. A. Harris of Cambridge, "The rheumatic child is highly strung but he isn't neurotic." I realized then that I had been "barking up the wrong tree" in looking for evidence of neurosis in these children. The important fact is their excitable temperament, demonstrated again by this small series of mine, but emphasized over many years by a number of clinicians. Cheadle wrote in 1889:

> "I would insist on the fact that there is nothing antagonistic between the agency of the nervous state or mental excitement and rheumatism. They are concerned together as factors in many cases of chorea." And again: "I should like to call attention to the relation of nervous excitability to rheumatism. The rheumatic children who develop chorea are intellectual, highly strung, excitable, nervous, often emotional. The question arises, Is the nervous instability due to the influence of the recent active rheumatic state and induced by it; or is the nervous instability part of the original constitution of the child, and chorea produced when this is acted upon by a second fact—viz., rheumatism? Or do the two tendencies run together in the original diathesis—the child with a tendency to rheumatism inheriting thereby a mobile nervous system?"

Still (1912) writes:

> "To my mind one of the most striking features in such children is the nervous temperament, to which Goodhart has specially drawn attention. The rheumatic child is *par excellence* the nervous child. In many cases this is seen in an undue excitability: such children will become almost uncontrollable in their excitement over games and amusements or, on the other hand, there may be excessive timidity; in some of the older children this is replaced by a sensitivity or shyness which is almost morbid."

This description of the rheumatic child's temperament has been elaborated by many authors, but the quotation from Still described it well enough—the excessive excitability disguised often by shyness but wildly expressed in moments of acute emotion. It has often been suggested that this nervous excitability is the result of rheumatic infection, but Neustatter's investigations do not support such a theory. He concludes that the "rheumatism may aggravate the nervousness but does not cause it." This has also been my experience. The mothers of these children related that the excitability was present for years before the development of the rheumatic state. Therefore studies of the child's personality during and after the development of the rheumatic state will have equal validity with studies made before; and they should be more informative, since the child's nature has been exposed to the most searching of all tests—a recognition that the heart, the organ whose beating signifies life and whose stillness means death, is diseased. Poynton (1936) said of this emotional disturbance, in the Harben Lectures:

> "We must understand the child with acute heart disease. It may be instinctively terrified to a high degree, just as an adult may be when he or she feels that the very pivot of life is in danger."

Winnicott (1938), who has studied these children for many years as a paediatrician and later by psycho-analytical technique, writes:

> "When we examine the child's heart we do not always realize that in the child's unconscious fantasy we are testing his ability to keep his ideals alive and unhurt. The child does not necessarily understand the life and death of his body as we understand it, but he understands something deeper which is the life or death of what he believes in and values most in himself. What we say, therefore, about the things inside to which we listen with a stethoscope and discuss with our colleagues over a bedside comes to the child as a matter of life and death in an acutely real sense. It is a matter of reality and of the right to live. In adult terms, it is to be or not to be, to continue to live or to seek death. These are the anxieties that belong to psychiatric depression."

It makes little difference whether we choose to talk of instinctive terror with Poynton or in terms of unconscious fantasy with Winnicott, the important fact for practising physicians to realize is that we are dealing with children who are suffering from fear—unexpressed, unrecognized, and undischarged.

Neustatter suggested that the symptoms—night terrors, restless sleep, worrying disposition, timidity, swings of mood, and emotional instability—which were commoner in his rheumatic groups have an aetiological distinction from the neuroses: "the former are possibly of primarily physiological origin and the latter due to psychological causes." This idea is an illuminating extension of Prof. Harris's remark quoted above, but its expression and the juxtaposition of "physiological" and "psychological" are not happy. It is preferable to regard the temperament of these children as showing a quantitative difference from normal—a speeding-up of both motor and emotional reactions—while the neurotic displays a qualitative deviation from normal. It is possible that the electroencephalogram may one day diagnose and measure for us this quantitative deviation.

No one can deny the emotional and kinetic lability of the child with chorea, but it is as legitimate to deny as it is to assert that this excitability exists also in many rheumatic children. Nor do I see how, in the present state of our knowledge, these matters can be put to scientific proof. There is no laboratory test for acute rheumatism, nor is there any objective measurement of excitability; investigation can only be by question and answer and by subjective observation. Any one physician caring for any one rheumatic child has to attempt the assessment of these factors for himself.

It is concluded that where the rheumatic child displays neurotic symptoms, as he or she infrequently does, these symptoms are superimposed on a nervous temperament and stand in no aetiological relation to the rheumatism. It is suggested that the personality of the rheumatic child shows a quantitative increase in emotion and kinesis—which has long been recognized by many clinical observers—and it is suggested that this nervous instability is an important factor in the development of the rheumatic state.

Treatment of the Nervous Rheumatic Child

There are two principles in the treatment of these children which are implicit in all that has been written here. The first is that the child, whether suffering from nervous disorder, growing pains, arthritis, or chorea, should not be regarded as suffering from the rheumatic state until the diagnosis of carditis is definitely established. The second is that evidence of nervous excitability or instability should be sought and, if found, treated in all such children before, during, and after the development of this rheumatic state. The first principle will prevent the formation of cardiac neurosis, and the second principle, I believe, gives the best hope of limiting the extent of the rheumatic disorder in childhood.

Nothing recondite is required in the way of psychiatric diagnosis and treatment for these children. They are nervous and timid, excitable and fearful, and the appropriate treatment is by way of reassurance, recognition, and solution, if possible, of environmental difficulty, and by sedatives.

Reassurance.—The need for reassurance should be remembered at every stage of treatment. Words spoken at the bedside should be definitely encouraging: no hint of diagnostic difficulty, of therapeutic failure, or of doubtful prognosis should be allowed to reach the child. Attempts should be made by parents, doctors, and teachers to overcome the child's timidity and fear. He should be encouraged, by every means to believe that his background is stable and his environment secure. The best means to this end is to surround him with a confident family circle. The already anxious mother will be quick to catch the physician's dominating fear, which is the fear of relapse, and the family atmosphere seldom brings reassurance to these children. Fortunately, most of these children are much less fearful of the effect of physical activity than are their mothers and doctors.

Winnicott (1938) has written: "It may be said that once we have diagnosed rheumatism implying that the child is liable to heart disease our job is to produce in the child an *induced hypochondria.* This is our first task, and the future depends on our success rather than on drugs." No doubt this holds a certain element of truth, but it also holds a greater element of danger. Hypochondria will not help to return the child to normal living; and this last must surely be the object of all therapy. It is important to recall constantly, when treating rheumatic heart disease in children, that a cardiac neurosis is frequently imposed on these children. Paul White (1937) reported that 4.7% of patients with organic heart disease had "neuro-circulatory asthenia"; and Paul Wood (1941) found that out of 100 recruits with early organic heart disease 13 showed the symptoms of Da Costa's syndrome. I believe that once the active rheumatic process has subsided (and of this we can to-day furnish good evidence with the sleeping pulse rate and the sedimentation rate) the child should be returned to normal living as quickly as possible, and its activity should then be limited, not by some imposed standard but only by the heart's capacity. I believe that nervous relapse (chorea and subacute rheumatism) is best prevented by the methods outlined here. The prevention of further pharyngeal infection presents a difficult problem. The removal of large numbers of these children to Florida has been shown not to prevent it. Schlesinger (1938) has shown that continuous aspirin therapy reduces the liability to streptococcal relapses; it is probable that continuous sulphonamide therapy will prove itself more effective (Thomas, 1942). I believe that no measures should be taken to prevent infection which interfere with the child's normal living.

Environmental Difficulties.—These may be related to the family or to school. In neither case is removal from the family or prolonged absence from school likely to offer a permanent solution. It is amazing how light-heartedly children are kept away from school. The child that cannot adapt itself to its family has failed at its first hurdle, the child that cannot adapt itself to the normal educational stresses has failed at its second, and such children are unlikely to succeed at the later stages of the race. An attempt should be made to iron out the grosser environmental stresses, but the aim should always be to alter the child's abnormal reactions to its environment.

The Value of Sedatives.—I believe that continuous sedation by phenobarbitone is first-class therapeutics for these children with growing pains and the subacute rheumatic state, with chorea, and with active rheumatism. It will no doubt be objected that there are dangers in this continuous treatment by sedatives. I can only say in reply that I have watched these children for several years and am convinced that their physical and mental performance is improved by such therapy.

Growing Pains.—The child is depressed, weeps easily, sleeps badly, and is worried by pains. In time its anxieties appear to be related entirely to its physical symptoms. "There, I'm flushing again: My heart's beating away: I can't eat my dinner: I've got that pain in my legs: Why can't I stop twitching?: I shall never get to sleep." These are the cries of the child, and phenobarbitone causes the symptoms to disappear.

Chorea.—I believe that every child who has had chorea should be treated with phenobarbitone daily until after puberty. I have had 12 unselected children who have suffered from chorea under continuous observation and such treatment for periods varying from three to six years. Only one of them has had a relapse of chorea and only two have had another rheumatic episode in the period of observation. This is much less than the expected relapse rate for such children. Other observers have found that it is possible to reduce the expected relapse rate in chorea by the attempt to remove environmental stress but without continuous sedation. Gerstley and his collaborators recorded a relapse in only 6 children out of 45 with chorea over a period of seven years, and "three of those had not been faithful attendants at the clinic." Their prophylactic treatment was "by keeping the youngsters under constant observation, obtaining co-operation from the school teacher, and avoiding the radio and thrilling movie."

The Rheumatic State.—All children with acute rheumatism should be given sedatives, since all are liable to chorea. Such therapy is more important for girls than for boys, and more important for children who have had previous attacks of chorea. As to the need for sedation in the other phases of the rheumatic state, the physician must assess the instability of the individual child. I have formulated for my own use the following rules for the administration of phenobarbitone to these children. It should be given to all rheumatic children who (1) show undue excitability, timidity, or motor instability, (2) show disorders of sleep, digestion, or appetite; (3) complain of fatigue or other "circulatory" symptoms unrelated to physical activity (i.e., the common complaint of tiredness in the morning). As an example of the results of this treatment the following case is related:

A girl aged 12 was admitted to the hospital for the first time in April, 1941. She had been known to have a "weak heart" since an examination by the school medical officer at the age of 5. She had not been allowed to play games, go to the gymnasium, swim, or cycle. She has always slept badly and had a poor appetite. Her weight was 4 st. 12 lb. before her present illness. Her mother said she was very excitable and, although usually happy, was liable to violent outbursts of temper. These outbursts were generally related to imposed restriction of her physical activities. She had an attack of rheumatism after measles at the age of 8, but had had no other rheumatic episode since. Examination of her heart showed pericarditis and fully developed mitral stenosis. Her sedimentation rate was normal in six weeks, and she was allowed out of bed in ten weeks. She returned home and has had 1/2 gr. of phenobarbitone night and morning since. She sleeps well, has a good appetite, and has gained 20 lb. in the last year. She is said to be happy, even-tempered, and much less excitable. She rides a bicycle, has learnt to swim, has spent a week under canvas at a girls' camp, and has had no time away from school.

It is suggested that the treatment of these children by simple psychotherapy and by sedation removes their growing pains, reduces relapse in chorea, and improves the mental and physical performance of the rheumatic child.

Summary of the Argument

The rheumatic state in childhood has two main components—nervous excitability and infection. These two factors are present in varying degree in any one rheumatic child, so that it may be impossible in one child to distinguish any nervous instability or in another to detect any certain evidence of infection. In one, the profound motor and emotional instability which is called chorea may possess the child and infection be either absent or a late invader; while in another, infection dominates the scene at the abrupt onset and throughout the subsequent course.

It is concluded that growing pains are usually the result of some difficulty attending the growth of personality, not of stature, and that it is more easy to find evidence of nervous instability than of infection in the subacute rheumatic state.

The nervous instability of the rheumatic child has no relation to neurosis; it is suggested that it is a quantitative increase in emotion and kinesis. The relationship between the nervous excitability and the infection is difficult to determine. It has been generally assumed that such nervous instability as is allowed to the rheumatic child is the direct result of the "rheumatic infection or toxaemia," and this view is supported by the fact that chorea may develop for the first time during an attack of acute rheumatism. There is more evidence to support the contrary view that this nervous excitability in the child commonly precedes the onset of infection and may even prepare the ground for the rheumatic invader.

The various aetiological factors in the rheumatic state are potent in so far as they predispose to these two components—nervous excitability and infection. Age, sex (as in chorea), and the nervous stresses of poverty are important since they contribute to the appropriate nervous excitability; climate, cold and damp, overcrowding, and the other physical accompaniments of poverty are important because they increase the liability to droplet infection. The heritable factor in the rheumatism of childhood cannot be of great importance, since there are many facts that declare it primarily an environmental disorder.

Glover (1930) has called rheumatism an obsolescent disease, and this no doubt depends on the slow removal of the appropriate environmental stresses amongst the poor. Such "gradualness may be inevitable," but it is suggested that the health of the rheumatic child is improved and stabilized by treatment of its nervous instability. This is done by the removal of the grosser environmental stresses, if possible, by the adjustment of the child's reaction to its environment, and, most important of all, by continuous sedation with phenobarbitone.

I am grateful to Lieut.-Col. Paul Wood, R.A.M.C, for much helpful criticism in the revision of this paper.

MACROCYTIC ANAEMIA OF PREGNANCY AND THE PUERPERIUM

BY

H. W. FULLERTON, M.D., M.R.C.P.
Department of Medicine, University of Aberdeen

It is generally believed that the macrocytic anaemia, or so-called "pernicious anaemia," of pregnancy is due to a lack of the anti-pernicious-anaemia principle brought about by one or more of the following causes: (*a*) a temporary depression of secretion of the specific intrinsic factor of Castle (Strauss and Castle, 1933; *Brit. Ency. med. Pract.*, 1936); (*b*) a deficient intake of the extrinsic factor (Strauss and Castle, 1933; *Brit. Ency. med. Pract.*, 1936); and (*c*) a diversion to the foetus of the anti-anaemic principle itself (Vaughan, 1936). The usual conception of treatment is that it is similar to that of Addisonian pernicious anaemia except that in the macrocytic anaemia of pregnancy it may be discontinued after delivery, when the demands of the foetus no longer exist and a return of the secretion of intrinsic factor has been presumed to occur (Strauss and Castle, 1933; Vaughan, 1936). The three cases to be described are of interest because there was little or no improvement in the blood level after liver extracts given parenterally, but rapid regeneration occurred when this treatment was supplemented by the ingestion of whole liver.

Case I

Mrs. A., aged 39, was admitted to hospital in Nov., 1941, during the 36th week of pregnancy. For two weeks before admission she felt tired and breathless and vomited frequently. The pregnancy had until then been uneventful, and she had taken a diet which was notable in only one respect—namely, that she had never cared for and seldom ate any red meat. She had five children, all alive and well. The last child was born in Nov., 1937, and at that time she was noted to be severely anaemic and was given a blood transfusion after labour. Next day the haemoglobin was 30% and a film was described as showing the features of pernicious anaemia. In the next 13 days 40 c.cm. of campolon was injected. Reticulocyte counts apparently were not done, but it is of interest that 15 days after the first injection the haemoglobin had fallen slightly to 28%. Large doses of campolon were continued, and recovery was then rapid. She was discharged with a haemoglobin of 70%; no further treatment was given. There seems little doubt, therefore, that she had had "pernicious anaemia" of pregnancy in 1937.

When seen in Nov., 1941, she was obviously severely anaemic. Physical examination revealed no notable abnormality. The tongue and nails were normal. Free hydrochloric acid was secreted after the injection of histamine—maximum, 30 units at one hour. The haemoglobin was 20%, and the other findings were compatible with Addisonian pernicious anaemia except that anisocytosis was less than would be expected at this level. A Price-Jones curve gave a mean cell diameter of 8.5 μ.

In the first three days 10 c.cm. of campolon and 8 c.cm. of anahaemin were injected (see Fig. 1). Three days after the first injection there was a reticulocytosis of 9.7%. On this day delivery occurred and a blood transfusion of two pints was given. The blood loss after delivery was estimated at about one pint. The slight improvement produced by the transfusion was transient and the blood count had fallen almost to the initial level on the tenth day. From the eighth day onwards daily injections of anahaemin or neo-hepatex and small doses of campoferron orally were given. On the sixteenth day there was a reticulocyte crisis of 40%, but very little rise in the red cell count occurred. On the fourteenth day treatment with whole liver was begun. The reticulocytes were 29% on the thirtieth day, and the blood count then rose rapidly.

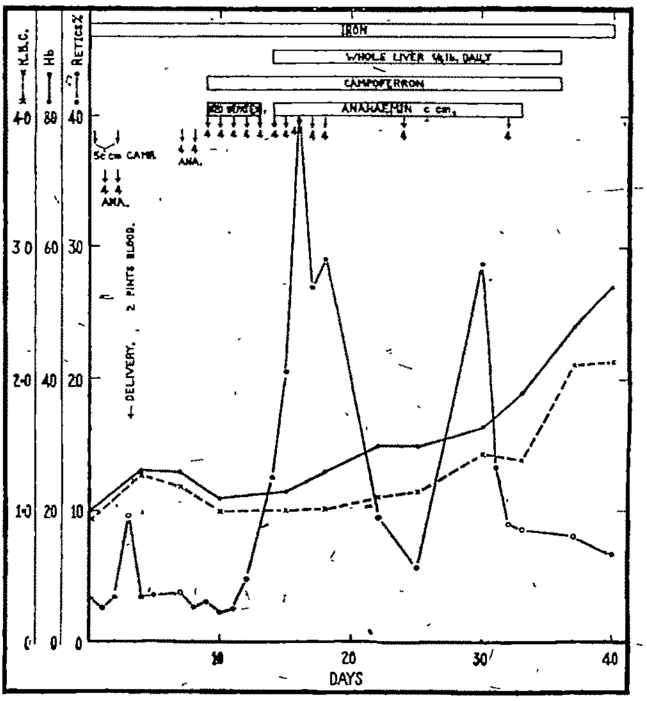

FIG. 1.—Chart of Case I

Case II

Mrs. B, aged 39, was admitted to hospital in June, 1941, five weeks after giving birth to her sixth child. She insisted that she had no untoward symptoms until three weeks after delivery, when she began to be breathless and tired; but she was inclined to belittle her symptoms, and it is quite possible that their onset was earlier than this. At the same time there developed a burning pain in the tongue, and her appetite, which previously had been excellent, began to fail, so that shortly before admission she had literally to force herself to eat. Her diet appeared to have been satisfactory, and was distinctly better than that taken by most women of the hospital class.

The tongue showed no papillary atrophy, but there was a superficial ulcer on each margin. The spleen was easily palpable four fingerbreadths below the costal margin. Free hydrochloric acid was secreted after the injection of histamine. The initial blood count was: Hb 27%, R.B.C. 1,400,000, C.I. 0.96, reticulocytes 3.7%, W.B.C. 3,100 (see Fig. 2). The appearances in a film were compatible with Addisonian pernicious anaemia. Sternal marrow showed 55% of erythroblasts, with 18% of megaloblasts. Following injection of 2 c.cm. of anahaemin there was a small reticulocyte response (maximum 7.6% on the fourth day), but in spite of this the blood count fell slightly. On the seventh day after beginning treatment with whole liver, campoferon, campolon, and anahaemin the reticulocytes reached a peak of 27%, and this was followed by extremely rapid blood regeneration, the haemoglobin rising by 60% and the red cells by 3 millions in the 18 days following the start of this treatment. The patient has been seen at intervals for six months, and has maintained a normal blood count without further treatment.

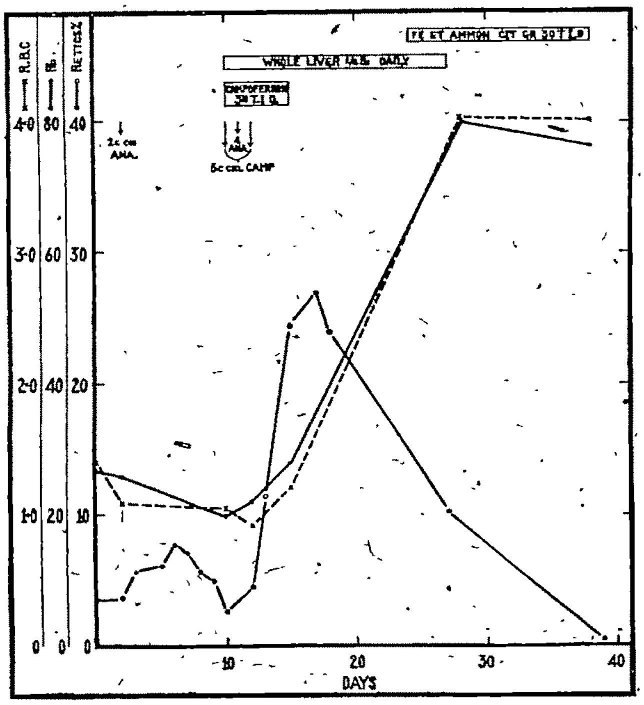

FIG. 2.—Chart of Case II.

Case III

Mrs. C., aged 36, was admitted to hospital in Sept., 1941, 6 weeks after giving birth to her ninth child. Immediately after labour she felt weak and tired, and these symptoms gradually became more marked. For about a week before admission there were diarrhoea and pain in the tongue. Her appetite was good until the last two months of pregnancy, and she had always taken a good mixed diet. In this case there was histamine-fast achlorhydria, and the tongue papillae were atrophic. The initial blood count was: Hb 18%, R.B.C. 650,000, C.I. 1.30, W.B.C. 3,600, reticulocytes 14% (see Fig. 3). The film was indistinguishable from that of Addisonian pernicious anaemia. A Price-Jones curve gave a mean cell diameter of 7.88 μ, and the mean cell volume was 92.6 cu.μ. The sternal marrow showed 28% erythroblasts, including 8% megaloblasts.

A reticulocyte response of 27.5% occurred 11 days after the injection of 4 c.cm. of anahaemin and 7 days after 10 c.cm. of campolon. The blood count, however, rose only slightly, and then gradually fell. Seven days after beginning treatment with whole liver and daily injections of neo-hepatex there was a reticulocytosis of 28.6%, and another peak of 20% occurred 6 days later. At the same time the blood count began to rise very rapidly.

Discussion

That the macrocytic anaemia of pregnancy and the puerperium may be refractory to treatment which is efficacious in Addisonian anaemia is not well recognized, and it is not clear whether this fact is due to its rarity or whether it has been largely overlooked. A study of the literature shows that cases of this type have occurred (Stevenson, 1937-8; Ungley, 1938), but little emphasis has been laid upon them, and in a recent review by Sodeman (1940) they receive no mention. In the discussion which followed a communication based on the cases reported here (meeting of the Association of Physicians of Great Britain and Ireland, April, 1942), L. S. P. Davidson described a series of 16 cases of macrocytic anaemia occurring in pregnancy and the puerperium of which 10 were temporarily refractory to treatment with massive doses of liver extract. Details of these cases have been published by Davidson, Davis, and Innes (1942). Now that attention has been drawn to cases of this type it is possible that they will be found to form a considerable proportion of the macrocytic anaemias associated with pregnancy.

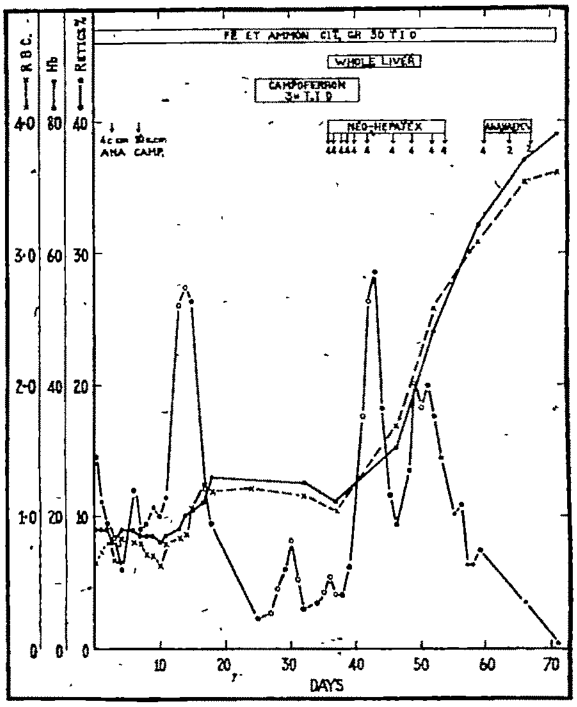

FIG. 3.—Chart of Case III.

It is unfortunate that in each of the cases reported above the degree of anaemia was so severe that the separate trial of different therapeutic agents was not justified. Accordingly, massive treatment with parenteral liver extracts, campoferron (oral liver extract with iron; Bayer Products Ltd.), and whole liver was instituted in each case after the effect of parenteral liver extract had been found to be slight or absent. This makes interpretation of the results more difficult than would have been the case if the different forms of therapy had been used separately, but analysis of the results appears to justify certain conclusions.

In Cases I and III large doses of campolon (Bayer Products Ltd.) and anahaemin (British Drug Houses Ltd.) produced reticulocyte responses but little or no rise in the blood count, while in Case II 2 c.cm. of anahaemin brought about a small reticulocyte response but no improvement in the anaemia. All the liver extracts used were potent; for example, the same dose of the same batch of anahaemin as was used in Case II produced an optimal reticulocyte response and rapid blood regeneration in a case of Addisonian pernicious anaemia. Moreover, there was no evidence of sepsis or other condition that might have had an inhibitory effect, and the rapid blood regeneration which followed massive therapy makes it clear that marrow hypoplasia was not present. It may be concluded, therefore, that a deficiency of factors other than the anti-pernicious-anaemia principle was concerned in the production of the anaemia. The evidence suggests that the ingestion of whole liver provided these factors. It might be argued that they were present in low concentration in the parenteral extracts used, and that these extracts in the very large doses given were responsible for the ultimately satisfactory blood regeneration. This possibility seems unlikely, since Cases I and III showed little or no rise in the blood count after quite large initial doses of campolon and anahaemin. Moreover, the concentration of such additional factors in liver extract is likely to be much greater in crude preparations like campolon than in the refined extracts anahaemin and neo-hepatex (Evans Sons Lescher and Webb), and it is seen from Figs. 1 and 3 that campolon was not given during the period of massive therapy which produced rapid blood regeneration. The effect of campoferron can probably be discounted, since the dose given was small, and when used alone for 11 days in Case III this preparation produced a small reticulocytosis but no rise in the blood count.

Attention is drawn to the double reticulocyte response which occurred during the period of massive therapy in Cases I and III. The phenomenon was not discernible in Case II, perhaps because of the infrequency of the observations during this period. The time relationships of these reticulocyte crises suggest that the first was due to parenteral therapy, and the second to the ingestion of whole liver. The occurrence of this second reticulocytosis, and the fact that it was accompanied and followed by rapid blood regeneration, are further evidence that whole liver provided essential factors which were not present in the parenteral extracts.

The characteristics of the responses shown by the cases under discussion suggest an analogy with the macrocytic anaemia of sprue and other steatorrhoeas, in which it has been noted that in some cases blood regeneration does not follow the reticulocytosis produced by parenteral liver extracts unless a high protein diet is also given. Davidson (1939) has described a case of this type and suggested that the high intake of protein might be necessary for the formation of red cell stroma. Of particular interest is the fact that one of the constituents of the diet used in his case was 1/2 lb. of liver daily. Moreover, I have recently studied 3 cases of macrocytic anaemia associated with steatorrhoea which were refractory to parenteral extracts but responded rapidly when whole liver was given without any other alteration in the diet. It is hoped to publish these cases at an early date. These observations suggest that in cases of macrocytic anaemia of pregnancy and the puerperium of the type here described there may exist a deficiency of factors present in whole liver similar to those which are lacking in some cases of macrocytic anaemia associated with steatorrhoea. The nature of these factors and the causes which produced deficiency in the cases described are quite obscure. Certainly the histories do not point to direct dietary deficiency, and although a temporary depression of absorption from the intestine brought about by the pregnancy would explain the findings, there is no direct evidence that such a condition existed.

Summary

Three cases of macrocytic anaemia of pregnancy and the puerperium are described. The results of treatment showed that deficiency of the anti-pernicious-anaemia principle was not the only factor concerned in the production of the anaemia. Reticulocytosis after injection of liver extract may not be followed by remission in the macrocytic anaemia of pregnancy. The administration of whole liver appeared to provide other factors necessary for blood regeneration. An analogy is drawn between these cases and the macrocytic anaemia associated with steatorrhoea.

Taking advantage of the investigation by bronchoscopy of patients suffering from various pulmonary lesions, L. Tuft and N. M. Levin (*Amer. J. med. Sci.*, 1942, **203**, 717) took samples of bronchial secretion before and after the intravenous injection of sodium iodide. The iodide was detected in the bronchial secretion within 15 to 20 minutes after intravenous injection. The authors believe that the excretion of iodides into the bronchial tree accounts for their expectorant action.

ECONOMY IN FATS AND OILS IN TREATMENT OF SKIN DISEASES

BY

G. H. PERCIVAL, M.D., Ph.D., F.R.C.P.Ed., D.P.H.
Physician to the Skin Department, Royal Infirmary, Edinburgh

In September, 1939, it was realized that the shortage of fats and oils which would inevitably occur might in time seriously affect the treatment of diseases of the skin. It was then recommended that wet dressings and varnishes should be used whenever possible in place of ointment and paste preparations. Such substitution is not, however, universally applicable. Just as some types of inflammatory skin diseases, particularly inflammatory processes of the eczematous type, are intolerant to greasy applications of all descriptions in certain phases of their course, so other inflammatory conditions, including most cases presenting the eczema type of inflammation, demand grease in some form if a response to treatment is to be achieved. These well-known facts can only be interpreted as showing that processes or reactions which occur at the point of contact between the epidermal surface on the one hand and the opposing surface of the vehicle containing the therapeutic agent on the other have a profound influence on the course of the disease, and this quite apart from any known pharmacological action of substances incorporated in the vehicle. Greasy bases are therefore essential and irreplaceable in dermatological therapy.

A substantial quantity of a greasy base must be used in the treatment of a case. For example, 2 lb. of a paste containing 15% zinc oxide in paraff. moll. is necessary for a single adequate dressing of an eczematous eruption involving the entire body, 6 oz. for an arm and hand only, and 3 oz. for a hand and fingers only. Less is required if zinc oxide or other inert powder employed to give the paste consistence is omitted; but it has been pointed out that the nature of the base may be all-important and determine success or failure with an incorporated drug, and it frequently happens that the paste consistence is essential. To remove a paste from the inflamed skin a preliminary softening and cleansing with a mineral or vegetable oil is necessary, followed by washing with soap and water. The oil and soap add to the total amount of fats and oils used in the treatment of the disease.

As there is no substitute for grease, economy in its use can only be achieved by some procedure or manipulation that eliminates the necessity for using oil and soap in conjunction with it, and this can be done.

Skin-cleansing Substances

The following substances can be added to a bath in small amounts or used in the same way as liquid soap; they will remove from the skin a paste containing 15% zinc oxide without a preliminary cleansing of the skin with oil:

Sodium salt of highly sulphonated oleic acid (M 1337)*
Polyethenoxy-ether of cetyl alcohol (M 1344)
The sodium salt of the sulphuric ester of sperm oil alcohol (M 1773)
Cetyltrimethyl ammonium bromide

These substances have been used as cleansing agents with no deleterious effect on acutely eczematous skin. They are not primary irritants and, except in the rarest instances, are not substances to which idiosyncrasy may be expected. The latter statement can of course be applied to any widely used skin application or skin contact substance, either therapeutic or cosmetic, or to wearing apparel.

The removal of a pomade with a soft paraffin base which has been thoroughly rubbed into the hair and scalp in the female is an extremely arduous and frequently disappointing procedure when soap preparations are used, but these substances can completely and easily cleanse such a scalp.

---

* These substances are standardized mixtures to which it would be difficult to assign a precise chemical definition, and for this reason a number is appended to a general descriptive nomenclature.

Emulsifying Agents

Another method of economizing in oil is to incorporate an emulsifying agent in the ointment base. The following formulae have been tried:

		Parts
℞	Paraff. moll.	25
	Octadecyl alcohol	2–4
	Diethylene glycol distearate	2.5–5
	Sodium cetyl sulphate (15% paste)	1
	Water	22–26

This emulsion must be kept in a closed container to avoid evaporation.

℞	Tetraethenoxy-cetyl alcohol	10–20 g.
	Paraff. moll.	ad 100 g.

℞	Cetyl alcohol — 4 mols ethylene oxide ..	40	parts, of this 10–20 g.
	Cetyl alcohol	40	
	Sodium cetyl sulphate ..	20	
	Paraff. moll.		ad 100 g.

To these preparations may be added any of the ingredients commonly incorporated in the ointment bases—i.e., zinc oxide, ichthammol, mercury, sulphur, etc.

These three formulae have been used with the addition of 15% zinc oxide and an active ingredient such as ichthammol or ammoniated mercury in the treatment of a sufficient number of eczematous skin eruptions to give convincing evidence that they fulfil the same conditions as regards suitability as was found in the case of the cleansing agents. To remove these preparations from the skin no oil is required, and considerably less soap is used than is necessary when a cleansing oil has been applied before the soap and water in the removal of an ordinary paste base; sometimes it is possible to dispense with soap altogether.

Comment

In the case of the cleansing agents, oil and soap are dispensed with; in the case of the emulsifying bases, oil is not necessary and little or no soap is used. The extent of the economy which might result from the employment of these preparations or others of similar nature can be judged when the oil and soap consumption of a large department for the treatment of skin diseases is examined. The weekly requirement in one such department containing 60 beds and catering for the daily treatment of from 20 to 30 out-patients referred from the consultation-room is about 400 oz. of oil and 12 lb. of soap. In addition to economy in actual material there is a considerable reduction in the time required to carry out treatment. To prepare for a bath a case in which a paste has been applied to the entire body surface at least half an hour's work with oil is necessary, and at least part of this operation requires the services of a nurse.

Finally, the removal of ordinary pastes necessitates a considerable amount of friction, which has some temporary deleterious effect on the course of an eczematous eruption. The employment of either type of preparation described above obviates this drawback.

My thanks are due to Imperial Chemical Industries (Pharmaceuticals) Ltd., Manchester, for the preparations used in this investigation.

THE BREAD FACTOR IN A WARTIME HUMAN DIETARY

BY

MARION B. RICHARDS, M.A., D.Sc.

(From the Rowett Research Institute, Aberdeen)

Contradictory statements have appeared in the literature as to the merits or demerits of national wheatmeal bread and of the proposals to fortify this bread with calcium in the form of creta praeparata or white bread with aneurin (vitamin B_1) and calcium in the same form. It was thought, therefore, to be of interest to record the results of some feeding experiments recently carried out with rats.

The experiments were designed to determine the effect on the growth of young rats of substituting national wheatmeal bread or fortified white bread for the ordinary white bread in the basal diet. This basal diet was drawn up from the results of a dietary survey carried out in a North of Scotland town in the spring of 1941, and represents the average diet of a number of families spending up to 7s. per head weekly on food. The rats' basal diet contained all the various foods in the proportion in which they were found in the human diet. The methods used in the preparation of the food, which was in all cases fed *ad lib.*, were similar to those described for an earlier dietary experiment at this institute (Orr, Thomson, and Garry, 1936). Since "fortified" white bread was not available in this part of the country, white bread supplemented with chalk and aneurin in the proportions officially proposed was employed for this purpose.

Experiment I

In the first experiment six groups of rats were used, and the diets and weight increases for each group over a period of eight weeks are shown in the accompanying table. The rats were given their respective diets at weaning, approximately half of them being taken from the stock colony, the others being the offspring of parents which had been reared on the corresponding experimental diets in a preliminary experiment. Each group contained 14 or 15 males and 15 females, the sexes being caged separately. The mineral–vitamin supplement used in Group 5 contained calcium, phosphorus, iron, and vitamins A, B_1, and C in amounts such as would, if fed in proportion to the quantity supplied to the rats, have brought the daily intake of the members of the families surveyed up to Ca, 1 g.; P, 1.3 g.; Fe, 15 mg.; vitamin A, 4,000 I.U.; vitamin C, 1,500 I.U.; and vitamin B_1 390 I.U. (i.e., ratio to calories 1:5).

Table showing Diets and Weight Increases for Experiments I and II

Group	Diet		Males			Females		
	Type of Bread	Supplement	Initial Weight	Weight After 8 Weeks	Average Weekly Gain	Initial Weight	Weight After 8 Weeks	Average Weekly Gain
			g.	g.	g.	g.	g.	g.
			Experiment I					
1	White	—	42·4	191 9	18·7	40 4	149·4	13 6
2	N.W.M.	—	44·6	208·4	20·5	40 2	151·1	13 9
3	White	Ca+aneurin	43·7	228·2	23·1	42 1	168·0	15 7
4	N.W.M.	Ca	42 6	231 3	23·6	41 1	165·5	15·6
5	White	Vitamins+ minerals	43·7	227·3	23·0	40 8	166 9	15 8
6	White	Ca	40·3	205 9	20 7	38·5	156·7	14·8
			Experiment II					
2	N.W.M.	—	40·5	208·2	21·0	39 5	157·9	14·8
3	N.W.M.	Ca+aneurin	40 3	242 7	25·3	39·5	186 4	18 4
4	N.W.M.	Ca	40 3	246 9	25·8	39 9	183 6	18 0
5	N.W.M.	Vitamins+ minerals	40 3	259·1	27·4	39·2	192·5	19 2

The figures show that for the male rats the average weekly gain of 18.7 g. in the control group has been increased to 20.5 g. by the substitution of national wheatmeal for white bread. A similar increase (20.7 g.) was found in the group which received white bread with a calcium supplement. A greater improvement was found in the groups which received both additional calcium and vitamin B_1, whether the B_1 was given as aneurin or as national wheatmeal bread. In these groups the average weekly gains were 23.1, 23.6, and 23.0 g. Similar results hold also for the groups of females, except that the substitution of wheatmeal bread for white had little effect on the rate of weight increase. The marked improvement caused by simultaneous addition of calcium and vitamin B_1 was again observed.

Experiment II

Experiment II was intended to be a second-generation repetition of Experiment I, all the young rats in this test being the offspring of animals used in the growth tests just recorded. Unfortunately white bread was no longer available, so some modification of the groups was necessary. It was decided to test the effect of increasing the ratio of I.U. of vitamin B_1 to calories by adding extra aneurin. In Groups 2 and 4, which correspond to the groups of the same numbers in Experiment I, this ratio was 1:4.33. The amount of aneurin used as supplement for Group 3 brought this ratio up to 1:3, and the ratio for Group 5, with a mineral+vitamin supplement as in Experiment I (but with the complete B complex instead of B_1 alone), was 1:4. In this experiment each group contained 17 or 18 males and a like number of females.

The figures for the weekly gain in weight again show the beneficial effect of the calcium supplement. Thus for the males the average gain of 21.0 g. on the unsupplemented ration was increased to 25.8 g. by the addition of calcium, while for the females the figures were 14.8 and 18.0 respectively. The increased amount of aneurin given to Group 3 had little or no effect on the growth of the rats. The best response was shown by the animals in Group 5, which received the complete vitamin-mineral supplement. Here the gains averaged 27.4 and 19.2 g. for males and females respectively; but the greater part of the extra increase was undoubtedly due to the added calcium, as is shown by comparison with the results for Group 4.

Comment

These results point quite definitely to the fact that the addition of calcium to this diet in the amount which it has been proposed to add to national wheatmeal flour does not produce any harmful results, but, on the contrary, tends definitely to enhance the value of the diet as measured by the live-weight increase of young rats. On these figures there is no evidence in support of further additions of vitamin B_1 in the form of aneurin when national wheatmeal bread is used. In so far as they go, the data just cited support the findings of Gaunt, Irving, and Thomson (1938) that a poor human dietary of the type used in this experiment can be materially improved by supplementing with calcium in inorganic form.

Medical Memoranda

Anaesthesia for Laryngofissure

In view of the growing popularity of surgical treatment of carcinoma of the larynx it is important that an adequate anaesthetic technique should be evolved. In the past preliminary tracheotomy, with its attendant risk of chest complications, has usually been performed. The suggested method does away with the necessity for a tracheotomy and ensures post-operative haemostasis. In a recent series of 8 cases performed by Mr. Charles Keogh there were no post-operative chest complications.

Method.—Premedication: omnopon 1/3 gr. and scopolamine 1/150 gr. 1 hour before operation. Induction: anaesthesia is induced in the normal way with N_2O, O_2, and trilene, using a Boyle apparatus. When the patient is well into the third stage of anaesthesia a stiff gum-elastic intratracheal catheter, St. Bart's pattern, size 12–14, is passed through the larynx into the trachea under direct vision. Great care is taken to avoid the growth during this manœuvre. The proximal end of the catheter is now connected to the machine and anaesthesia is maintained with O_2 and trilene. Owing to the small bore of the tube it is usually necessary to supplement the volume of oxygen reaching the lungs by gentle intermittent pressure on the rebreathing bag with the expiratory valve fairly tightly screwed down.

Operation.—As soon as the incision has been made and the larynx opened the space between the catheter and the trachea is thoroughly packed off with narrow gauze, leaving one end emerging from the lower part of the wound. This ensures that no blood leaks down the trachea during the operation. The catheter is now found to lie in the posterior commissure of the larynx and usually interferes very little with the surgical procedure. If it proves to be in the way, then it may be retracted one way or the other. In only one case, where the growth was quite extensive, has this proved necessary. Anaesthesia is maintained as before with O_2 and trilene, aided by manual pressure on the rebreathing bag at each inspiration. Some of the gas percolates back through the packing in the trachea. As trilene is non-inflammable the diathermy may be used if necessary.

Haemostasis.—Following excision of the growth it is often very difficult to achieve perfect haemostasis. After removal of the tracheal packing and catheter the anaesthetist may play his part by passing a large-bore Magill tube, size 8–9, with inflatable cuff, through the nose and into the trachea under direct vision. When the cuff lies in the larynx it is inflated through the pilot tube until it occupies the lumen of the larynx and presses up against the field of operation. The laryngofissure is now sewn up, and the patient returns to the ward with a clear airway and a guarantee of haemostasis.

Post-operative Treatment.—The intratracheal tube is left in position for 8 hours. During this time the patient is given morphine, and a little 2% decicaine solution is sprayed down the tube from time to time. In only one case did the tube have to be withdrawn earlier than was desirable. In this case it had been passed through the mouth. Provided it is passed through the nose very little discomfort is experienced. Eight hours after the operation the laryngeal cuff is deflated. After waiting a few minutes the patient is asked to cough. If blood is coughed up through the tube, then the cuff is re-inflated and the same procedure repeated in 2 hours. If no blood appears, then the tube is gently but firmly withdrawn. Even this procedure causes remarkably little discomfort to the patient.

Conclusion.—The object of this technique is to provide safe anaesthesia for cases of laryngofissure without a tracheotomy and its accompanying disadvantages. Also it hinders the surgeon very little and assures him of post-operative haemostasis.

I am very grateful to Mr. Charles Keogh for his co-operation and valuable suggestions.

C. B. Lewis, M.R.C.S., D.A.,
Resident Anaesthetist, London Hospital.

A Combined Infection of the Throat with Diphtheria and Tuberculosis

I have failed to find in the literature any reference to such a combination, and am therefore of the opinion that the following case is worth recording.

The patient, a primipara about seven months pregnant, was admitted to Clayponds Isolation Hospital on Jan. 27, 1942, as suffering from diphtheria. The history given was that she developed a cold and cough on Dec. 27 and took to bed on Jan. 1. On Jan. 14 she had a sore throat, which she said was very swollen. On Jan. 26 vomiting began. Her doctor suspected diphtheria, and a throat swab taken that day was found positive for the diphtheria bacillus. On Jan 27 she was given 16,000 units of diphtheria antitoxin intramuscularly before admission to hospital and a further 40,000 units intramuscularly after admission.

When admitted a greyish membrane was seen to cover the left side of the pharynx, left tonsil and pillars of the fauces, and the adjacent portion of the soft palate and uvula. The condition bore a resemblance to the smooth greyish-white appearance sometimes seen after a diphtheria membrane has separated, but did not appear to me to be quite typical. The left cervical glands were moderately enlarged and tender. The general condition of the patient was poor. Her face had a greyish cyanotic hue and the pulse was weak and rapid. The throat affection continued to spread, and it became evident in the course of a few days that the condition was one of extensive shallow ulceration with a thin ragged edge and a granulating base. The patient also had a distressing cough and brought up a few ounces of purulent sputum daily. Tuberculosis was suspected, and examination of the sputum on Feb. 3 showed that tubercle bacilli were present. Throat swabs taken on Jan. 30 and Feb. 8 still showed the presence of diphtheria bacilli. The Wassermann and Kahn reactions were negative. Physical signs in the chest were slight; but there was some impaired resonance, and air entry in the right scapular area. From Feb. 3 onwards the temperature was irregular, there being an average evening pyrexia of 100° F. The patient's appetite was poor, vomiting was frequent, and her general condition had deteriorated. On Feb. 14 she passed a few ounces of dark blood per rectum and also vomited some digested blood, becoming very collapsed. Though she revived somewhat, her condition on the following day was very poor, and on the morning of the 16th she began to complain of lower abdominal pain. At 2.30 p.m. the membranes ruptured, and at 3.30 p.m. she was delivered of a healthy premature male infant weighing 4 lb. 10 oz. Labour appeared comparatively easy, and was followed shortly by delivery of the placenta and membranes complete. There was no undue haemorrhage. At 5.15 p.m. the patient suddenly complained of inability to breathe. She became very collapsed and dyspnoeic, and died in about 10 minutes.

A post-mortem examination showed the presence of a thin-walled tuberculous cavity about 1¼ in. in diameter at the right apex. There was acute tuberculous bronchopneumonia, with numerous small ragged cavities occupying the remainder of the right upper lobe. The tuberculous ulceration of the throat extended over the epiglottis, giving it an eroded appearance, and oedema and granulation of the vocal cords were present. The heart was dilated and the muscle pale and flabby; the liver was enlarged and pale from cloudy swelling. No other abnormality was discovered. The uterus was healthy and well contracted.

The condition of the baby was satisfactory. It gained weight rapidly, and was discharged from hospital in a thriving state. The Mantoux reaction was negative up to 1 in 100 dilution.

The extent and the rapid spread of tuberculous ulceration in the upper respiratory tract seen in this case were quite unusual, and it is interesting to speculate whether a diphtheritic infection acted in this instance as an aggravating or a predisposing cause. The natural resistance to tuberculosis was obviously so poor that recovery was not to be expected. It was not anticipated, however, that the patient would die so suddenly. The strain of labour on a heart affected with diphtheritic carditis would help to explain the sudden death. As I had not had the opportunity of seeing this case in the earlier stages of the throat infection I cannot altogether exclude the possibility of the diphtheria bacillus existing merely as a saprophyte in a tuberculous throat, but nevertheless consider that the case is of unusual interest.

My thanks are due to Dr. Thomas Orr, medical officer of health for Ealing, for his kind permission to publish this case.

Reviews

NASAL SINUSES

Nasal Sinuses. An Anatomic and Clinical Consideration By O. E. Van Alyea, M.D. A William Wood Book. (Pp. 262; illustrated. 36s.) Baltimore: The Williams and Wilkins Company; London: Baillière, Tindall and Cox. 1942.

Dr. Van Alyea has written a book on the accessory sinuses, of which he has made a special anatomical study. He has combined with this clinical descriptions which consist largely of quotations from the published articles of numerous writers, showing evidence of wide if rather undiscriminating reading. The anatomical descriptions are good, but they reveal nothing in any way new or original, and the same applies to the excellent illustrations. It is to the anatomy of ethmoid bone that Dr. Van Alyea has chiefly devoted himself, and he has investigated the variations in its cellular structure in much detail. This is the most valuable part of the book and is its principal justification. The author says himself that no effort has been made in the limited space to cover all phases of sinus disease, but this hardly excuses the unequal treatment of the subject. Thus much space is devoted to lavage of the maxillary antrum, but the vaguest account only is given of the major operations on the accessory sinuses. The same applies to the description of osteomyelitis of the frontal bone: the reader is left with only a misty account of its pathology and how it should be treated. There is, nevertheless, a vast amount of information in the book, but it is scattered and incomplete.

The real purpose of the book is not clear, but it will be read with interest by specialists. The author, however, might have made it more interesting and informative if he had relied more upon himself, and refrained from the uncritical quotations of at least half of the authors to whom he has made himself indebted. In several places this degenerates into nothing more than a review of the literature, much of which is of an ephemeral character.

A FIFTY-YEAR-OLD TEXTBOOK

The Principles and Practice of Medicine. By Henry A. Christian, M.D., F.R.C.P. Originally written by Sir William Osler, Bart., M.D., F.R.C.P., F.R.S. Designed for the use of Practitioners and Students of Medicine. 14th (semicentennial: 1892-1942) edition. (Pp. 1,475. Cloth, 45s.) New York and London: D. Appleton-Century Company.

Fifty years ago the medical world was startled by the appearance of a textbook planned on really new lines. Although Osler was already physician-in-chief at Johns Hopkins he was little known in this country, except for his demonstration of platelets in the circulating blood. The book had an immediate success and conferred international fame on the author, whose personality was subsequently realized to be even greater than his book. The story of its origin and accomplishment is well told in Cushing's *Life of Sir William Osler*. It proved to be the last great medical textbook by a single writer, and in the subsequent editions produced by McCrae and later by Christian, two of his pupils, the Oslerian tradition has been so far as possible maintained and a continuity of thought secured.

One significant rearrangement has, however, been made. The book opens with a short introduction on psychosomatic medicine, which is justified on the ground that "in later years, with the enormous development of laboratory procedures and the increased utilization of complex techniques of examining the patient, the physician has found it increasingly easy to neglect the patient's personality and surroundings in his management of him, with the resultant feeling on the part of the patient that he is missing something that is traditional of the general practitioner who served his forebears." Psychosomatic medicine, often looked upon as new, is in reality "what the former generations of medical men practised without much use of names for it." Conformably with this outlook, the first section of this book is now devoted to functional diseases of the nervous system, to emphasize the fact that "every patient with organic disease presents a functional, emotional reaction which varies with the personality, the economic and social relationships, and the race and heredity of the individual."

It is a herculean task for one man to revise an account of the whole field of organic disease and bring it up to date. The editor rightly claims continuity of thought, but his claim to balance in description is perhaps not always so fully substantiated. Thus considerable space is given to rare and tropical parasitic diseases, while affections of the spleen are cursorily dealt with. However, so long as the encyclopaedic method prevails, the desire to include some reference to everything inevitably renders such balance precarious. For the rest we have nothing but praise, and we anticipate as much popularity for the book in its new form as it rightly had in the old.

HUMAN CONTROL OF CLIMATE

Climate and the Energy of Nations. By S. F. Markham, M.A., B.Litt., F.R.Met.S. (Pp. 144. 10s. 6d.) London: Oxford University Press. 1942

The argument of Mr. Markham's pleasantly written and interesting little book is this. Modern research has demonstrated that the optimum working conditions indoors are given by an air temperature having a range of a few degrees above and below 70° F., with humidities ranging from 40 to 70%. Hence, in a social organization where artificial heating or cooling is unknown, optimum conditions will only be found near the annual isotherm of 70° F. But when men of genius, in a civilization able to profit from their genius, discover efficient means of warming and, eventually, cooling the atmosphere, so that maximal energy can be developed in colder (or warmer) natural climates, then the foci of civilization will or may move.

Mr. Markham sketches the history of civilizations and finds no facts inconsistent with this hypothesis. Human control of climate is a necessary condition of civilization. Perhaps Mr. Markham comes a little too near to suggesting that it is a sufficient condition, and has not allowed enough weight to the argument that disease, especially malaria, played a great part in sapping ancient civilizations. His rebuttal on p. 13 is *ad captandum*. Epidemiologically speaking, neither tuberculosis nor cancer, however energy-destroying, can have the nation-wide or continent-wide effects of malaria or hookworm disease. The book is well worth reading.

Notes on Books

The very practical textbook *A Glasgow Manual of Obstetrics*, by S. J. Cameron, John Hewitt, and Ellen D. Hewitt, is now in its fourth edition, the last three having been published in the short space of 6 years. Its popularity is well merited. The new edition, which is larger than its predecessors, records most fresh developments in the field of obstetrics while emphasizing the need for sound conservative methods. Two surprising omissions are that in the treatment of eclampsia credit is not given to the Dublin school for seeing the light and abandoning their 40-year practice of colonic lavage, and no reference is made to the condition of erythroblastosis, with which the modern student should be familiar. This very sound book is published by Edward Arnold and Co. at 25s.

The fifteen years that have elapsed since the first edition of Mr H. M. Traquair's *Introduction to Clinical Perimetry* appeared have seen considerable additions to our knowledge both of the normal field of vision and of pathological changes in it. Perhaps the most noteworthy developments have been angioscotometry and the clearer recognition of opto-chiasmic arachnoiditis. Colour fields at one time attracted considerable and perhaps undue attention, and it is a measure of Traquair's knowledge, balanced judgment, and powers of exposition that the plan of his book has hardly changed throughout the four editions it has now reached. The present edition carries amplifications and additions derived from the more recent literature, and the book remains the indispensable guide for ophthalmologists and neurologists that it has been from the beginning. It is published by Henry Kimpton at 30s.

Of several books on sulphonamide chemotherapy Wesley W Spink's *Sulfanilamide and Related Compounds in General Practice* is, we believe, the first to appear in a second edition. It has been rearranged and considerably enlarged, the chief subjects more fully dealt with being the general principles of treatment and the mode of action of these drugs, their local application, and the treatment of intestinal infections. The book contains much information of great practical value, and is as nearly up to date as a publication on a rapidly progressing subject can be: the latest work on succinyl sulphathiazole and promin is naturally not included, although both compounds are mentioned. The tabular statements giving an order of preference for each of four drugs in a large number of different conditions (now 60) and of the frequency and import of various toxic manifestations, both of which we ventured to criticize as perhaps unduly dogmatic, are still included, and anthrax still figures mistakenly in the list of diseases for which sulphonamide compounds are of no value. The book is published in America by the Year Book Publishers, and in London by H. K. Lewis at 18s.

BRITISH MEDICAL JOURNAL
LONDON
SATURDAY FEBRUARY 6 1943

THE NEW ERA IN INDUSTRIAL MEDICINE

The sound of shears, if not of axes, might be expected to be heard in the report of a Select Committee on National Expenditure, but such a report just issued, on health and welfare of women in war factories,[1] is by no means a bleak document. Those who compiled it have had obvious difficulty in keeping within their terms of reference—namely, the economic impact of problems of industrial health on war expenditure—and have touched on a number of social implications. So far from retrenchment, they make some bold and timely recommendations which will cost quite a lot of money. They urge, for example, the enlargement and strengthening of the medical branch of the factory inspectorate of the Ministry of Labour. The thirteen medical inspectors at present attached to the inspectorate are there to advise on occupational hazards and to carry out research and inquiries into specific problems. In the opinion of the Select Committee their number is not adequate to provide advice and instruction on a wide scale, nor have they the authority to secure the acceptance of their advice where it is most needed. Another recommendation is for the setting up of industrial health advisory committees, central and regional, to advise the Ministry of Labour, supply departments, regional boards, and employers on questions of industrial health, co-ordination of medical services, and the like. These would be channels in which information and advice would be conveyed down to the smallest factory. A central bureau is also proposed to keep factory doctors, nurses, and welfare staff abreast of recent knowledge and developments.

All this may well presage the opening of a new chapter in industry. Hitherto health services in industry, with all that they can effect in reducing the incidence of industrial disease, have depended principally upon arrangements made by firms who were progressive enough to realize their importance and large enough to justify the engagement of medical and nursing staff. No clear standards of industrial health have been worked out. Central direction has been lacking. The Ministry of Health does not include all health services in its brood, and this is one of the unincluded. The Ministry of Labour lacks the necessary organization to deal with these problems. At present there are only 150 whole-time and 582 part-time doctors employed in industry. In addition there are the examining factory surgeons, to the number of nearly 2,000, whose work is ordinarily that of examination of juveniles and inspection of processes. No doubt the work of these examining surgeons now includes some of the duties which fall to part-time works medical officers; but as there are over a quarter of a million factories in this country it will be realized that the amount of supervision which can be exercised by this small body of medical men can cover adequately only a fraction of the industrial population. Many defects are pointed out by the Select Committee, such as the lack of any close relationship between those who are working to maintain health inside the factories and those concerned with outside medical services—the works medical officers on the one hand and insurance practitioners, hospitals, and public health services on the other.

One important point is that the status, remuneration, and security of tenure are not such as to attract doctors into the field of industrial medicine. But the medical profession itself has recognized the need for a better industrial service. It was only in 1941 that the B.M.A. Committee's report on industrial health in factories was published, with its call for an extension of industrial medical service on both humanitarian and economic grounds, for more emphasis on the preventive aspects of industrial medical practice, and for closer association between the medical profession and industry. The Select Committee recommends that the Government should give the closest attention to the problem of securing a satisfactory industrial medical service, at least in all factories engaged on Government work, and in this connexion it considers that more use should be made of women doctors.

The circumstance which has led up to these proposals is the entrance on a large scale of women into industry. One and a half million women are now employed in industry who were not so employed in mid-1939. Large numbers of them have had no previous experience of factory life. A considerable proportion are married women, with their own special problems. Except in Royal Ordnance factories and certain private undertakings there has been no selective medical examination on entrance. Many women have been directed to work away from their homes. From various accounts these transfers have not always been carried out with much imagination. Women have been sent a considerable distance, and then it has been discovered that they are unfit, by reason of illness or mental disability, for the work to which they have been assigned —a thing which might sometimes have been obvious even to the lay official. Only the present scarcity of medical staff prevents the Select Committee from recommending that careful medical examination should be made in every case before a woman is transferred. The Select Committee makes a score of recommendations concerning hours of work, rest pauses, amenities, safety precautions—in 1941 the number of reportable accidents to women was 42,837, nearly three times as many as in 1940—and many other items in the management of personnel. It urges that plans be proceeded with for the early diagnosis of tuberculosis by mass radiography, that means of rehabilitation be provided for the injured worker, that visual standards be established for various factory processes, that attention be given to ventilation in factories, the more important in view of the black-out—often daytime black-out—conditions. It goes outside the factory and suggests that a pregnant woman should be eligible for unemployment benefit for two months before her confinement, as well as for a suitable period afterwards, to enable her to breast-feed her infant. Maternity benefit under National Health Insurance, whereby the mother receives £2, or a maximum of £4 if both she and her husband are insured, is insufficient, especially at such a time, when her earnings usually cease with her employment.

The entrance of women into industry has caused many misgivings. Women have special needs and are subject to special strains. Factory amenities that might be disregarded in the case of men assume a critical importance in the case of women, and the Committee even concerns itself with such questions as the colour of the walls in rest rooms—deprecating whitewash—and the provision of mirrors in wash rooms. What is more important—hours of work which are suitable for men may be too lengthy for women. We learn of one transport undertaking which began to employ conductresses under the same conditions as men, but within three months the women went on deputation to the management and said that they were unequal to the hours, and the schedules were revised and the pay readjusted accordingly. Another recommendation of the Committee is that women personnel managers and welfare officers should play an important part in selecting, interviewing, and allocating woman labour. "A man frequently does not appreciate the needs and difficulties peculiar to women." We hope that the new colour and pattern which the entrance of women into the factories is giving to industrial health and welfare organization will be permanently wrought into the industrial life of the future. The Select Committee says: "The State cannot afford to be other than a good employer." And if the State cannot afford it, neither can any private undertaking.

CIRRHOSIS OF THE LIVER

The term "cirrhosis" was introduced by Laennec for a condition which in many ways presents as enigmatic a problem as any other in medicine. There has consequently been no shortage of descriptive terms and attempts at classification: atrophic and hypertrophic cirrhosis, portal, biliary, and Hanot's cirrhosis, mono- and multi-lobular cirrhosis, and "hob-nail" or "gin-drinker's liver" have all had their vogue. Out of chaos an orderly system is now perhaps emerging which will mean something to the clinician. The tendency now is to recognize two main types—namely, portal and biliary (obstructive and infective). Hanot's cirrhosis is perhaps no longer a recognizable anatomical entity; healed yellow atrophy is being brought into line with cirrhosis. But we still seem to be far from a complete understanding of the aetiology and pathogenesis of cirrhosis. The cells of the liver are bathed in blood brought by the portal circulation and so are exposed to any noxious agent that travels along this well-worn route. According to the nature and extent of the injury a few may die; reaction may be severe or mild, or repeated, or slow and insidious; whatever the beginning, the end may be cirrhosis.

Moon,[1] in a comprehensive review, emphasizes the destruction of architectural pattern as a criterion of true portal cirrhosis, and states that of all the chemical agents used only a few have produced true portal cirrhosis—namely, carbon tetrachloride, phosphorus and alcohol together, manganese chloride and phenylhydrazine, and chloroform combined with infection. Chronic alcoholic poisoning is now almost off the list of cirrhogenic agents, and room on it is now being found for dietary factors, in either excess or deficiency. According to Earle and Victor[2] an excess of cystine in the diet produces fatty infiltration, portal haemorrhagic necrosis, a high mortality rate, and cirrhosis in all rats surviving more than two weeks. This cirrhosis is similar to that produced by selenium in rats and unlike that produced by some of the poisons mentioned above. These observations are in line with those of György and Goldblatt,[3] who found that in the hepatic injury of dietetic origin (necrosis and cirrhosis, with or without ascites) determining factors seem to be connected with the lipotrophic action of casein. Previous experiments[4] showed that focal or diffuse necrosis was observed in rats fed on a diet devoid of the vitamin-B complex, supplemented with aneurin, riboflavin, and pyridoxine. They believe that the lipotrophic action of casein is in direct proportion to its content of methionine and to the presence of choline in the diet, and that it is reversely influenced by *l*-cystine and supplements of fat. Relating this to human cirrhosis, they point out that a low intake of protein with insufficient supply of the vitamin-B complex (including choline) is a prominent feature of the diet of persons addicted to alcohol: it is as unnecessary to postulate an injurious effect of alcohol in cirrhosis as it is in the pellagra or beriberi of alcoholics. Some corroboration of the reported beneficial effect on cirrhosis in man of a highly nutritious diet supplemented with the vitamin-B complex comes from Patek and Post,[5] and from Lowry *et al.*[6] of the beneficial effect of choline, high-casein diet, or choline with a high-casein diet in rats with hepatic cirrhosis produced by low-choline and low-casein diet with added cystine. In Patek and Post's clinical trials after the onset of ascites, 72% of a treated as compared with 50% of an untreated series survived six months, and at the end of two years the percentages were respectively 45 and 21. There were also signs of bodily improvement and presumptive evidence of arrest of the disease. They suggest that there is an aetiological relationship—either direct or indirect—between nutritional deficiency and cirrhosis of the liver. Lack of essential factors might lead directly to the development of the disease, while the malnourished liver becomes more vulnerable to toxins. Spellberg *et al.*[7] produced cirrhosis of the liver in rabbits and fatty liver in guinea-pigs by feeding the animals on apparently adequate diets containing 20% of fat—chiefly butter fat—although some factor other than diet might have been responsible. It was recognized that the rabbit is not altogether satisfactory as an experimental animal because of the common occurrence of coccidial infection. In view of these results, those of Rao,[8] suggesting that the infantile cirrhosis of Hindu children (a variety of portal cirrhosis) is caused by a diet of cows' milk combined with *B. coli* infection, must be seriously considered. There is scope for further work along these lines. The study of spontaneous cirrhosis in animals in this field should not, however, be excluded, and reference might be made to the interlobular fibrosis in the liver of the normal adult pig, the more common occurrence of cirrhosis in the pig than in any other animal, and the fact that cirrhosis in the pig produced experimentally by carbon tetrachloride closely resembles the naturally occurring lesions.[9]

THE PATHOGENESIS OF PEPTIC ULCER

A recent paper by Ask-Upmark[10] attempts to throw new light on the pathogenesis of peptic ulcer. Impressed by the frequency of peptic ulceration after all types of experimental damage to the liver, he contends that liver dysfunction is an essential factor in the aetiology. His experimental evidence consists of a study of post-mortem material and a series of tests of hepatic function in 26 cases of peptic ulcer. In 22 necropsies of hepatic cirrhosis he found 9 instances of chronic peptic ulcer. For his liver tests he used two varieties of the galactose-tolerance test, the Sjöström citric acid test, the Takata-Ara reaction, and the lipase determination of Rona. If all the tests are taken into consideration, 19 of the 26 cases of ulcer showed some abnormality of hepatic function.

The author considers that there is no evidence that the liver disturbance is secondary to abnormalities in the stomach, and he discusses at some length the mechanism whereby the liver might influence the stomach and duodenum. He favours the view that liver damage causes hypoglycaemia, which exerts an influence on gastric secretion. There is considerable evidence that hypoglycaemia does occur in peptic ulcer. The similarity of hunger pains and night pains to the symptoms of hypoglycaemia is quite striking, and the favourable effect of the administration of carbohydrates on the pain of peptic ulcer is also well recognized. The behaviour of the blood sugar in peptic ulcer has been studied by Christlieb,[11] who finds definite abnormalities in the glucose-tolerance test, the blood sugar rising too high in the hyperglycaemia phase and falling below normal limits in the hypoglycaemia phase. Ihre[12] has shown that insulin in the presence of hypoglycaemia is a powerful stimulant of gastric secretion, causing a rise in the pepsin concentration as well as hypersecretion. This is a vagal mechanism and can be abolished by cutting the vagi or by the use of atropine. Ask-Upmark shows that there is a relation between the liver and the central nervous system, citing as an example Wilson's disease (hepato-lenticular degeneration). He gives interesting case histories, where in one patient head injury, and in another encephalitis, were followed by gastric ulcer and evidence of liver damage. He concludes that the development of ulcer is mutually influenced by the liver and the central nervous system, but that probably the nervous influence is the more important. He visualizes the following chain of events: the hypothalamus, acting on a liver with impaired function, produces hypoglycaemia, which through a vagal reflex causes hypersecretion, this in turn leading to ulceration.

Most of us will find this chain about as difficult to visualize as the Indian rope trick. A more plausible explanation of the connexion between the liver and peptic ulcer has been provided by Cheney.[13] Superficial erosions develop in the gizzards of chicks fed on a diet which is deficient in a fat-soluble factor, occurring in association with, but definitely separate from, vitamin K. The same kind of lesion can also be produced by administering cinchophen to chicks, and the erosions become ulcers which closely resemble peptic ulcers in man. These cinchophen ulcers are more pronounced the more deficient the diet, and Cheney suggests that the ulcer-producing properties of cinchophen are due not to direct action on the lining of the stomach but to indirect effect on the liver. Damage to the liver may then interfere with the elaboration and storage of the anti-ulcer factor and its delivery to the stomach wall. The distribution of the "anti-gizzard erosion factor" is wide, and a direct deficiency in human diet is unlikely, even under conditions of war; but the possibility of a deficiency conditioned by a disturbance of the liver is well worth bearing in mind at the present time, when gastritis and peptic ulcer present such a formidable problem, and when potential liver poisons are widely used in industry and in the manufacture of munitions.

STARVATION IN SOUTHERN FRANCE

A moving plea that the blockade be lifted to allow 3,000 tons of food to be sent to Marseilles to preserve for another year the lives of 100,000 children in Southern France was made at a recent conference in London by Mr. Howard E. Kershner, director of relief of the American Friends Service Committee. Mr. Kershner spoke from personal experience in France of feeding French children since the Franco-German armistice. An acute food shortage was produced in Southern France in 1940 by the flood of refugees which in some towns multiplied the normal population by ten, and there had been no recovery. Failure of local production was due to absence of farm labour, enforced slaughter of farm animals, and shortage of fertilizers and seed. In this part of France, Mr. Kershner declared, three-fourths of the children were losing weight. Children who should have gained 4 to 5 cm. in height had gained only 1 to 2 cm.; often a gain in height was accompanied by loss of weight. Athletics had been given up in the schools, where the children sat about too weak to play. Newborn babies were usually about two-thirds of the normal weight; weights of infants had fallen to little more than one-half, and infant mortality had climbed up to three times the normal. He had seen grown men who weighed no more than 75 lb.

For two years his Service Committee had supplemented for 100,000 children the meagre French ration, on which it was scarcely possible to keep alive. This supplementary food had not come through the blockade: it had been accumulated previously from various sources in Central Europe, Africa, and Asia, even as far away as Indo-China; but these doors were now closed. A milk distribution scheme was organized, and it was remarkable to see how the weights of infants, which had been steadily decreasing, flattened out as soon as the milk distribution was made, and presently began to ascend; but the United States Government had refused permission for payment to be made for additional supplies of powdered milk which it had been arranged to buy in Switzerland.

Mr. Kershner, meeting an obvious objection, said that in his experience not a mouthful of food had been lost to the Germans, who had not interfered with the relief operations. Germany to-day was not taking as much food from France as she was entitled to take under the terms of the armistice, for the reason that the food did not exist in sufficient quantities to make it economically possible to take it away. If the British and American Governments would allow this extra food to enter the country it could be sent over in neutral ships (Swedish or Portuguese), the International Red Cross was willing to accept the responsibility, and 140 non-American workers in Southern France would feed the children. The food was available in abundance in America. In the interests of shortening the war and making reconstruction less difficult, he urged that the necessary facilities to save the life of the children of starving Europe should be granted.

TREATMENT OF DIABETIC COMA

Joslin and his co-workers[1] have recently reviewed their results in the treatment of diabetic coma since 1923. Since that time 525 patients have been treated, with a total mortality of 11%, and, since 1940, 62 consecutive cases without a single death. These striking results deserve close study. The American workers find that the commonest cause of coma is laxity in treatment either through dietary indiscretions or through failure to take the proper amount of insulin; the next is infection; in a third group coma is the first recognized sign of diabetes. Death cannot be correlated with any single symptom or sign, and the prognosis can be assessed only by the consideration of many factors, particularly age, degree of shock, blood pressure, depth of acidosis, blood sugar, plasma carbon dioxide, and blood non-protein nitrogen. Of these the single most important consideration is the depth and duration of unconsciousness before the institution of treatment.

The treatment of diabetic coma is essentially a hospital procedure, and preparations must be based on the realization that it is an acute medical emergency for which early, prompt, and vigorous treatment is absolutely essential. The medical, nursing, and laboratory staff should be organized to this end. As coma is due primarily to insulin insufficiency, adequate insulin dosage is the first consideration, and the first 50 units should often be given at home or on the way to hospital. On arrival the first dose should be between 20 and 100 units subcutaneously, and if the patient is unconscious and shocked a similar dose may be given intravenously. Further doses are then given half-hourly or hourly, the average patient needing at least 200 units in the first two or three hours. Subsequent dosage depends on the initial blood sugar response. If this is slight, larger doses of insulin should be administered more frequently, and it may be necessary to give 100 or more units at half-hourly or hourly intervals. The level of the blood sugar, the urinary sugar, and the clinical conditions—especially the mental state and the type of breathing—are the most valuable guides.

[1] *J. Amer. med. Ass.*, 1942, **119**, 1160.

Next in importance in treatment is the administration of fluids and salt, and isotonic sodium chloride solution, either intravenously or subcutaneously, should be begun at once, four to five litres in the first 24 hours being an average amount. Relatively more should be given by the mouth as recovery takes place. Other important measures include gastric lavage (which should be performed carefully on admission in almost every case), enemas, and small feeds such as broth, gruel, or tea with sugar by the mouth after about the first six hours. Dextrose is contra-indicated during the first few hours of treatment because there is already excess in the body fluids, and to give more masks the response to insulin. Alkalis are also considered unnecessary. Patients with prolonged unconsciousness and peripheral circulatory failure with very low blood pressure respond best to large doses of insulin and continuous saline infusions, with additional transfusion of plasma or whole blood in selected cases.

In summing up, Joslin and his colleagues emphasize that coma should be prevented, and that the occurrence both of coma and of death due to it shows that someone has blundered. The key to success lies in the education of the diabetic patient and of his doctor. These conclusions and their application are of profound importance. However good the actual technique of treatment in hospital or clinic, the incidence and mortality of diabetic coma will not be appreciably reduced until every diabetic patient is taught how to look after himself and when to seek further medical advice, and until every doctor knows how to manage diabetes in the home. In this country, especially in rural districts, delay in making the diagnosis and getting the patient to hospital is sometimes so considerable that the best treatment comes too late. Diabetic coma is as grave and as dangerous an emergency as an acute abdomen, and must always be treated as such.

HELP FOR THE SHIPWRECKED

To be cast adrift in a small boat on the open sea with scanty provisions and only a hope of being picked up is a situation the obvious drama of which has always made a powerful appeal to the imagination. To be so closely confined within such a vast space, to be exposed to every extremity of climate night and day, to sail upon water in an agony of thirst, to watch the effect of all this upon one's companions, and to endure, must call in the highest degree imaginable upon those mental and moral resources which constitute the heroic spirit of man. In an island country this is an eternal theme, and any measure or effort that will help to maintain the lives of those that "go down to the sea in ships" will, in time of war especially, command the heartfelt support of all men and women. Although chance plays its haphazard part in survival from shipwreck, it can be helped or hindered, or even destroyed, by the conduct of those who escape immediate death by drowning, and especially by the behaviour of the man in charge of a lifeboat's company. This conduct must be based on principles of psychology and physiology. A hundred and fifty years ago a seaman's guide was published which on the basis of experience offered advice to the shipwrecked. "Hope, perseverance, and subordination should form the seaman's great Creed and Duty, as they tend to banish despair, encourage confidence, and secure preservation." This and other excerpts from the guide are given in another manual just published and entitled "A Guide to the Preservation of Life at Sea after Shipwreck."[1] It has been prepared by a special committee of the Medical Research Council and is yet one more practical witness to the imagination and flexibility of this institution, to which the medical profession is so profoundly indebted for its many and sterling services to this country in time of war. A full abstract of this valuable document is printed elsewhere in this issue.

B.C.G. VACCINATION

Little is heard to-day about B.C.G. vaccination; reports of its use in other countries reach us with difficulty or not at all. Yet methods of controlling tuberculosis are not so numerous or effective as to justify completely disregarding it, particularly when the incidence of the disease is rising. B.C.G. vaccination is extensively used in Russia: it is used to an increasing extent in certain parts of the United States; and in Sweden it is compulsory in nurses who are tuberculin-negative. Wallgren has recently reviewed[2] his experience in Göteborg, Sweden, a town with a population of 250,000, where some 1,069 persons, chiefly children, in contact with tuberculosis were vaccinated by the intradermal method from 1927 to 1937. Great care was taken to vaccinate only non-infected people by separating them from contact for at least six weeks and testing with tuberculin. Most children were also kept away from contact for two months after vaccination. There was a follow-up of the vaccinated children in 1938, and it was found that of 397 vaccinated soon after birth who subsequently remained in contact with tuberculosis none died of the disease, and in only three were mild tuberculous lesions detected later. The parents of only ten children refused vaccination, but of these ten who were not vaccinated five died of tuberculosis, and at least one other developed tuberculous disease. Wallgren rightly emphasizes other favourable factors associated with the vaccination—for instance, the period of separation from contact and the special care that may be given by relatives to these children afterwards. Discussing immunity against tuberculosis, he points out that, as in syphilis, specific immunity may protect against fresh tuberculous infection but not necessarily against the virus already present in the body. Similarly, the relative immunity acquired as the result of B.C.G. vaccination might lessen the severity of the primary lesions, but would not necessarily prevent chronic dissemination or progressive pulmonary tuberculosis later. If, however, it is true that mild primary tuberculosis in adolescence is less likely than extensive primary lesions to be followed by progressive pulmonary tuberculosis, B.C.G. vaccination might also be expected to lessen the risk of post-primary tuberculosis in young adults. In this connexion Wallgren recalls, as was also pointed out by Kayne[3] and Pagel[4] recently in this country, that progressive pulmonary tuberculosis in adolescence and young adult life may be a fairly recent sequel to primary infection. From this he concludes that there are good grounds for recommending B.C.G. vaccination of young people before leaving school and before they go out into the world; this is already the practice in a few Swedish towns. Finally Wallgren produces evidence in support of his thesis that the protection obtained from B.C.G. vaccination remains much longer than is commonly believed—often ten years and even more.

HELP FOR THE SHIPWRECKED: A PRACTICAL GUIDE

As announced on another page, the Medical Research Council has just issued "A Guide to the Preservation of Life at Sea after Shipwreck." The information given in this guide summarizes the pooled knowledge of sailors and scientists, and it is hoped that the pamphlet will be studied by officers of the Royal Navy and the Merchant Navy and by medical men. The members of the committee drawing up the guide were Surg. Vice-Admiral Sir Sheldon Dudley, Surg. Rear-Admiral G. Gordon-Taylor, Surg. Capt. M. Critchley, Prof. A. N. Drury, Surg. Cmdr. R. A. Graff, Sir Thomas Lewis, Dr. R. A. McCance, Air Commodore T. McClurkin, Squad. Leader T. F. Macrae, D.Sc., Dr. Spencer Nairne, Capt. R. Oliver-Bellasis, R.N., and Dr. B. S. Platt. The committee was appointed in October, 1941, at the request of the Medical Department of the Navy, with the following terms of reference: "To examine the conditions to which Naval and R.A.F. personnel may be exposed after loss of ships or aircraft, when they may be adrift in boats or rafts or isolated in the desert; to examine the physiological aspects of those conditions, with special reference to water requirements, exposure to extremes of heat and cold, food requirements and stimulants, and to frame practical recommendations." In the preparation of the pamphlet the committee makes special acknowledgment to Cmdr. N. D. Holbrook, V.C., R.N., and Cmdr. J. Quayle, R.D., R.N.R.

Almost everything, the introduction states, depends on the bearing and conduct of the officer in charge; experience has shown that comfort and chance of survival depend upon the frame of mind of the boat's company. The store of vital energy possessed by each member of the lifeboat's company should not be wasted by useless exertion or the development of a "bad frame of mind." The contents of the pamphlet are then set forth under the following main headings: "Routine Preparations and Precautions in the Ship"; "Action in Emergency"; "Abandoning Ship"; "Procedure in Lifeboat"; "The Treatment of Sick and Wounded"; "Lifeboat Ailments"; "Steps towards Rescue"; "Treatment after Rescue." The points of likely interest to medical men are summarized below.

Some Anticipations

First-aid outfits, if not hermetically sealed, should be inspected frequently; damp articles must be dried or replaced.

If bomb hits are expected and duties permit, the effect of blast or of fragments and the risk of being thrown may be minimized by lying flat on the deck with head and body hard against a ledge-side or deck. Some protection is afforded if one stands with the head against something solid. If there is risk of flash-burns from explosions the skin should if possible be covered, even though the clothing be only thin.

The shipwrecked have often suffered unnecessarily from lack of clothing. Therefore, in abandoning ship, waterproof and any extra warm clothing—such as blankets or Duffel coats—should be gathered up. Too much clothing is better than too little; it will protect against the sun as well as against the cold. A pair of dry socks should be carried in the pocket or in a waterproof package. Modern lifebelts, it is pointed out, will support a person in the water fully dressed and wearing sea boots. Every effort should be made to take extra water: "*Water is more important than food.*" Containers must be improvised. Water bottles or similar containers should be filled. "Masters who have appreciated the paramount importance of an adequate water supply have succeeded in improvising stowage for as much as 120 gallons per boat." It is not likely that more food will be needed than is stored in the lifeboat.

Going Over the Side

If a man has to go over the side of the ship, he is advised to go over the lower side if the ship has listed. Going over the upper side carries with it the risk of being hurt by barnacles and marine growths and of fracturing the ankles against the bilge keel. If the lower side of the listed vessel is the weather side, a man should jump into the water from the bow or the stern, whichever is the lower, so as to avoid being washed back on board. He should jump into the water feet first, and not dive. If the sea is covered with fuel oil he should hold his nose when jumping, and when swimming through a patch of oil should keep head and eyes high and mouth closed. The effects of contact with oil discharged into the sea are not, however, serious. Swallowed oil may make a man sick, and if it gets into the eyes cause temporary blindness. If a man has to jump from a ship into burning oil, he may, if a good swimmer, avoid being burnt. He should jump feet first into the flames, swim as long as possible under water, then spring above the flames to breathe, taking a breast stroke to push them away; then back under the water again. Men have been able to traverse 200 yards of burning oil in this way. It is evident that the lifebelt and other cumbersome clothing should be removed to make it possible to do this.

Many men, it has been pointed out, have been drowned through panic action and thrashing about in the water. A man should look for a lifeboat, raft, or other floating object, and swim slowly towards it; he should not exhaust his strength by swimming about uselessly. Swimming or floating on the back lessens the danger of injury from under-water explosion.

Adrift

Energy must be conserved in the lifeboat. Singing and shouting, for example, use up strength, and cause loss of valuable water in the breath. Each man, unless badly wounded or exhausted, should have a job to do, however small. All wet clothing should be squeezed as dry as possible, but clothes should not be taken off for this purpose unless the weather is warm and dry and the wind moderate. Special attention must be paid to the feet. Wet socks and boots should be taken off and dry socks put on—and the boots too, when dry enough. If there is risk of "immersion foot," then boots are better removed from the start if the feet can be well covered with socks, wrapping, and waterproof clothing; boots should be left on if the feet cannot be kept dry, but must be removed once swelling of the feet is noticed.

Protection must be afforded against cold winds, rain, and spray, and against sun and heat, by means of canvas or wooden screens or an awning. In the heat too much clothing should not be taken off, as it protects the skin against sunburn. Legs and feet should be kept covered or in the shade. The wearing of a shirt or vest and headgear kept wet by occasional soaking in sea-water will afford some protection against tropical sun. Fuel oil, and greasy preparations such as ointment, tend to "fry" the skin and should not be used against sunburn. The glare of sun on the water may be minimized by tying a cloth or bandage over the nose. Bathing once or twice a day is allowed provided that no sharks or other biting fish are about, nor any stinging jellyfish nor Portuguese men-of-war. Sharks apparently are not as dangerous as reputed, and when they rub themselves against the lifeboat are more often than not trying to rid themselves of sea-lice.

Water and Food

The officer in charge must plan the rationing of water from the start. The size of the ration depends upon the likelihood of being picked up. If this is not likely to happen for a week, then no water need be given during the first 24 hours unless the men have been sweating from hot weather or exhaustion. The ration recommended is 18 oz. per man daily, which should be continued until there is one pint per man in hand; the ration must then be reduced to 2 oz. a day. It is pointed out that it is foolish and even dangerous to ration water on, say, a 60-day basis when there is a good chance of being picked up in 10 days. The experience of survivors suggests that moistening the lips and rinsing the mouth out with sea water are helpful, and also that small quantities may be used for soaking biscuits. "There is, however, no doubt that large draughts of sea-water cause death, and even small amounts may prejudice a man's chances of survival on a long voyage. Permission to *drink* sea-water, therefore, should never be given." Rectal administration of sea-water does not relieve thirst and is harmful. It is recommended that every drop of rain-water should be collected, and that no tin or vessel which can hold water should be thrown away. Pools of water formed of melted ice on ice-floes, provided they are not brackish from salt-water spray, may be drunk. The drinking of urine is harmful and should be forbidden.

If water rations are low, the food rations should consist mainly of fats, starches, and sugars, and should contain only small amounts of protein. The quantity of salt included in the food should also be small. Fats, besides providing concentrated energy, allay hunger better than other foods, and for this reason a biscuit with a high fat content is recommended. Pure butter-fat is the best kind of fat, and keeps well in airtight containers even in tropical climates. Foods rich in protein increase the body's requirements of water and should be avoided. Spirits have no thirst-quenching value and may be dangerous. If available they can be given to severely wounded men to secure sleep and ease pain. It is pointed out that owing to the small amount of food eaten the bowels will probably not act, and that the quantities of urine passed will diminish, but that this need not cause alarm.

Keeping Awake

Between watches it is important to get regular sleep. When fatigue increases, the man at the tiller or on watch may find it difficult to keep awake. He should then use the "energy tablets" provided—methedrine or amphetamine (benzedrine). If it appears that the whole party may be overtaken with severe exhaustion, it is considered better that all should keep awake, and that "energy tablets" should be issued. They are said to "(1) lessen feelings of fatigue and exhaustion, promote alertness, raise the spirits, and prolong the will to 'hang on' and live; (2) prevent sleep." Methedrine or amphetamine should be given when men are beginning to be worn down by hardship. If the shipwrecked are in Carley floats, rafts, or dinghies, and conditions are severe from the outset, tablets should be given at once—two at sunrise, at midday, and at sunset. If the conditions improve the tablets should be stopped. It may be dangerous to drop off to sleep in a Carley float, as the risk of drowning is increased. As a lifeboat party must be prepared to hold out for long periods, the tablets should not be used in the first few days. Single doses of two tablets may be given for special purposes—for example, to the man at the tiller, or when a special effort is necessary. If the whole party is overcome by exhaustion each man is given two tablets at sunrise and sundown. They should not be given to the wounded, to the excitable or hysterical, or to those whose minds are wandering.

A list is given of the first-aid equipment, and details of the Schäfer method of artificial respiration. There are also practical instructions on the emergency treatment of wounds, broken bones, burns and scalds, and shock. Among the short practical hints for the treatment of lifeboat ailments, dangling the hands in the sea is recommended as an aid to urination when this is felt to be difficult.

Frostbite

Two conditions are treated at greater length—namely, frostbite and "immersion foot." Frostbite at sea is rare unless the sea water is freezing. The skin, and sometimes deeper tissues, become actually frozen, the damage being caused by minute crystals of ice forming within the skin, which turns pale and yellowish-white, looks opaque, and feels of "wooden hardness." The actual freezing occurs suddenly and may pass unnoticed, as will the spread of the frozen patch. On thawing, the skin becomes inflamed and blistered. After severe freezing the part frozen dies and comes away after "blackening." Frostbite of the face may be detected by wrinkling it up to detect areas of stiffness. Small frozen areas may be thawed rapidly by covering them with a warm hand. Larger areas severely frostbitten, such as a whole foot, should be thawed gently by placing it inside a companion's clothes. Frost-bitten skin should not be rubbed with snow or otherwise. In the treatment of frostbite in a rescued person the thawed part should be put in cold, not warm, water, the rest of the patient being warmly wrapped up. On thawing, if the pain is severe, the part may be cooled for a short time with cold water, ice, or snow; and after thawing warming up must be gradual. The limb must not be warmed in front of a fire or by the application of hot water or bottles. The affected part should be cleaned and dried gently, dusted with sulphanilamide powder, wrapped in clean material, and kept at absolute rest.

Immersion Foot

"Immersion foot" is different from frostbite. The term is applied to damage of tissues immersed many hours in cold water or mud. The limb immersed is painful, red, numb, and weak. Numbness and weakness increase, and the limb swells. If immersion ends and the limb is warmed, early signs of damage quickly disappear. If the immersion lasts for days, damage will be more serious and blisters or dark patches appear, and the skin become broken. The damage, it is pointed out, comes from cold, and the chief source of cold in boats is cold water, out of which the feet should be kept if possible; also, if possible, boots should be emptied and socks dried. Feet and toes should be moved frequently. If the feet are swollen, numb, or tender, rubbing the skin will do more harm than good. In the treatment of immersion foot in a rescued man the affected limb should be kept cool, the rest of the body being heated. The limb should be warmed only gradually, and heating or rubbing it in any way is harmful. The temperature of the skin should be reduced to about 80° F., but not much below 70° F.; it can be taken by placing a bath thermometer against the skin under a covering of cotton-wool.

Correspondence

Surgery of Oesophageal Cancer

SIR,—In your annotation (Jan. 9, p. 48) you very kindly refer to my case of successful removal of the thoracic oesophagus by the "pull-through" method. But it would be unfortunate if this plan was regarded as purely a feat of prestidigitation, for it was deliberately planned after most careful consideration and prolonged study of the anatomical and pathological features involved, so that in no sense could it be described as "a trick." Although at the present time I regard the transthoracic operation as the best for dealing with growths of the mid-part of the gullet, I am not prepared to say that the "pull-through" method will eventually be entirely superseded. In all operations I like to work under the direct guidance of the eye, but none the less it must be admitted that sometimes blind procedures, like suprapubic enucleation of the prostate, are singularly successful. It is significant that the "pull-through" method has proved successful in the hands of other surgeons, and I would refer you to a well-illustrated account of the method together with the record of a successful case by Prof. A. W. Fischer from the University Clinic at Gieszen (*Arch. klin. Chir. Sonderabdruck*, 1937, ans. 189). In a personal communication I was also informed that a second successful operation had been carried out by one of Prof. Fischer's assistants. Unfortunately patients suffering from this disease still reach the surgeon when the condition has advanced beyond the wall of the oesophagus, which has consequently become fixed by infiltration to some of the surrounding structures; or there is involvement of the lymph nodes. The most important thing for the profession to realize is the necessity for thorough investigation of all cases of dysphagia at the outset. In this way a delay of many weeks could be avoided, and it might even be possible for a fair proportion of such cases to reach the hands of the surgeon while the disease is still limited to the walls of the gullet.

The surgery of malignant disease of the oesophagus is still in the experimental stage and there are many unsolved problems in connexion with its development, but whatever method of approach is to be employed the earlier it can be undertaken the better the chance of success.—I am, etc.,

G. GREY TURNER.

Filaria Worm in Eye

SIR,—I was very interested in Squadron Leader M. C. Reilly's note (Jan. 23, p. 103) on the removal of a filaria from the eye. Since 1937 I have seen two cases in the ocular adnexa, both patients having returned from abroad a few years previously. One was found in the upper lid and seized with forceps. Some novocain was then injected and the worm removed through a small incision. Apparently injection of novocain as a preliminary sends the worm post-haste in the opposite direction. The other was removed through the subconjunctival tissues in a similar manner to that described by Squadron Leader Reilly. Both were *Filaria loa*.

Duke-Elder has an excellent chapter in Volume III of his *Textbook of Ophthalmology* and quotes various cases dating from 1771 in which filaria have been found in almost every tissue of the eye—anterior chamber, iris, lens, vitreous, and retina—most of which, however, appear to relate to *Filaria bancrofti*, with successful removal in many cases. When the worm is seen in the anterior chamber, a keratome incision is made without loss of aqueous, and as the worm approaches the incision the lower lid is depressed and the worm floats out in the escaping aqueous. When inside the eye, the filaria may be tolerated for some time, but eventually considerable inflammatory reaction takes place, the majority of cases resulting in severe irido-cyclitis associated with keratitis. Duke-Elder makes the very interesting observation that intra-ocular filarial parasites are more common in animals than in man, and they have been found in horses, oxen, dogs, and even in frogs and fish.—I am, etc.,

Edinburgh C. R. DUNCAN LEEDS.

Orbicularis Oris in Facial Paralysis

SIR,—The subject of this letter may at first sight appear to be, but in reality is not, trivial. In a certain proportion of lower motor neurone facial paralyses there is almost complete recovery with the exception of a disfiguring retraction at the angle of the mouth on the affected side. For years one attributed this to contracture in certain muscles which had previously been the subject of flaccid paralysis, a phenomenon for which one was unable to find any analogy elsewhere. (The shortening of the muscles on the back of the forearm which sometimes follows a "drop" wrist would not be analogous.) It is now a good many years since I came to the conclusion—as no doubt other observers also have—that this facial deformity is due to non-recovery of the orbicularis oris, and consequent lack of opposition to the tone at rest, and activity in action, of the muscles which retract the angle of the mouth and whose motor nerve fibres have recovered. This constitutes a real disfigurement, and, in some, considerable psychological disturbance, and my object in writing is to suggest that it would seem to justify in itself the operation of decompression, which is hardly a major one, in the hope that the fibres destined for the orbicularis oris, possibly peculiarly exposed to pressure in the canal, may thereby be released.—I am, etc.,

London, W.1. ROBERT STANTON WOODS.

Phosphorus Poisoning from German Bullets

SIR,—Apart from drawing the attention of the profession to the possibility of fatal poisoning from the new types of German bullet, my main object in publishing my case (Dec. 5, p. 664) was in the hope of eliciting suggestions for treatment. The chief obstacle in eliminating the phosphorus or in rendering it innocuous before it gets absorbed into the circulation is the difficulty of reaching it, because the effect of the explosive charge scatters and spreads the phosphorus forcibly and deeply into the surrounding tissues. This deep infiltration would not occur, of course, in the case of the non-explosive type of phosphorus bullet described by Dr. J. R. F. Popplewell (Jan. 23, p. 111).

I have had communications from various sources, including such a high authority on toxicology as Dr. Roche Lynch, and I gather that there are only three commonly recognized chemical antidotes—i.e., copper sulphate, potassium permanganate, and hydrogen peroxide. A disadvantage of copper sulphate is that it is a poison itself, and is also locally deleterious to the tissue; further it would probably only act on the phosphorus lying in the superficial layer of the wound. Potassium permanganate 2% or hydrogen peroxide (half-strength) should cause no appreciable damage to the tissues, would be likely to penetrate more deeply (especially the hydrogen peroxide on account of its physical action), and could be applied continuously without detriment. The increasing difficulty in obtaining supplies of potassium permanganate and the expense in using large quantities point to hydrogen peroxide as the antidote of choice.

In treating a case of bullet wound the track of which is found to emit a phosphorus-smelling vapour, I recommend: (1) thorough opening up of the track, with extensive excision of all tissue practicable which shows any sign of damage; (2) irrigation of the wound with hydrogen peroxide—a weak solution at first for fear of a too violent reaction; (3) leaving the wound widely open and lightly packed with gauze, with Carrel's tubes placed in its depth; (4) continuous drip irrigation (or half-hourly irrigation) through these tubes with hydrogen peroxide half-strength; (5) administration of glucose, preferably by continuous intravenous drip, in order to assist the liver cells before they become irretrievably damaged.

In reply to Dr. R. E. Rewell's criticism (Jan. 9, p. 56) as to the incompatibility of having a high blood urea in the presence of liver necrosis, I would emphasize that the presence of these two conditions at the same time was an undoubted fact in my case. Facts may be stranger than fiction, and theoretical considerations must give way or be modified if they do not fit in with them. A scanty urine is known to be a phenomenon in acute phosphorus poisoning. Although the kidney damage does not appear to be great compared with that in the liver, the renal function may be impaired prior to the hepatic, and, if so, this might be an explanation of the high blood urea.—I am, etc.,

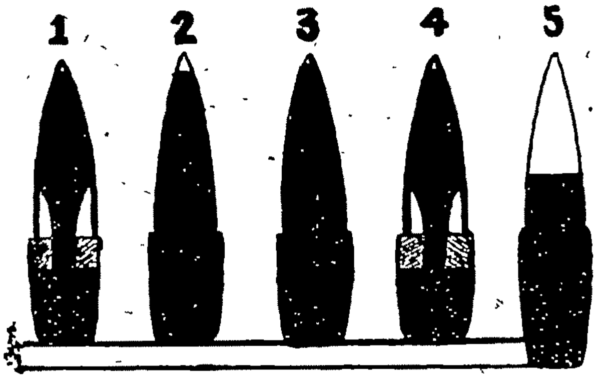
Norwich A. J. BLAXLAND.

German Explosive Bullets

SIR,—Dr. J. R. F. Popplewell in his letter (Jan. 23, p. 111) is to be congratulated for bringing some details of German explosive bullets to the notice of the medical profession, and for having had this ammunition examined, which procedure is not entirely devoid of personal risk. That the enemy was making use of a variety of types of ammunition in his aircraft has, of course, been known to the authorities of all three Services since the early stages of the present hostilities, although, as Dr. Popplewell correctly observes, "the medical profession as a whole were kept in the dark" on this matter. I do not know why.

The following additional details on this subject may be of interest to the medical profession generally, and assist them in their treatment of victims from enemy machine-gun fire. Early in 1940 I obtained a sample of ammunition taken from the machine-gun belt of a captured Messerschmitt, and on this I carried out an *x*-ray examination. It was found that the enemy was using five different types of ammunition arranged consecutively in the following order: (1) ball ammunition; (2) armour-piercing; (3) armour-piercing with tracer; (4) armour-piercing with incendiary; (5) explosive bullet.

The internal structure of all five types of these bullets was shown on the radiograph, but there appeared to be little difference in the internal structure of the ball (No. 1) and armour-piercing incendiary (No. 4), and also a similarity between armour-piercing (No. 2) and armour-piercing tracer (No. 3). The explosive bullet, however, is distinctive in having a semi-opaque distal half of the bullet, while the basal portion exceeds the length of any of the other four types by 0.3 cm. All five types of ammunition were, of course, sectioned and examined by an expert armourer, and the different types corroborated. The illustration above is a diagrammatic representation of the radiograph.



If an explosive bullet became lodged somewhere in the body and had failed to go off, a potential danger would exist to both the patient and the medical attendant. It might therefore be a wise precaution, in the interests of all, to have these casualties resulting from enemy machine-gun fire *x*-rayed before they are operated on, but, of course, excepting first-aid treatment.

It is just possible, in view of the above investigations, that the appearance of an explosive bullet would be determined by *x*-ray examination if the bullet was not too deeply seated in the tissues so that the appearance of the semi-opaque distal half became masked. I think the widest publicity of facts such as these should be made in the interests of the profession, apart from the help that this might render in the treatment of the patient.

In view of these observations, I should be interested to know if any medical practitioners in the country have been able to determine from an x-ray examination the nature of a bullet lodged in the body of a patient whom they have been treating.—I am, etc.,

London, W.1. NORMAN P. HENDERSON.

SIR,—In his letter under the heading "German Explosive Bullets" (Jan. 23, p. 111) Dr. J. R. F. Popplewell describes and depicts two types of the .312 Mauser bullets as used by the enemy in aircraft automatic guns. Type 1 is admittedly an explosive (and expansive) bullet in view of the soft nose and the detonating charge in its base; but Type 2 would appear to be incorrectly described as an explosive bullet. Is it not rather of the "tracer," "incendiary," and "anti-petrol-tank" variety?

If, as your correspondent intimates, many members of the public have come into possession of these projectiles they will do well to hand them over to the military authorities. Fulminate detonators are apt to explode to a slight shock, such as a fall off the mantelpiece, and the yellow or white phosphorus, apart from its toxic nature, is highly inflammable and liable to ignite should the oxygen of the air gain access to it.—I am, etc.,

CHARLES M. BEADNELL,
Towyn, N. Wales. Surgeon Rear-Admiral.

Pasteurization of Milk

SIR,—During my work over many years I have been greatly impressed with the diseases and, in some cases, fatalities due to the drinking of raw milk. These diseases have included not only tuberculosis but also a considerable number of *Brucella abortus* infections which have frequently been unrecognized. My experience is that undulant fever in its various forms is much more prevalent than is commonly supposed. I have, therefore, been strongly in favour of pasteurization to safeguard the health of the community. In my own household the rule has been that milk should be boiled, but it is impossible to arrange that members of one's family should not drink raw milk outside their home. One of these developed a severe form of undulant fever lasting well over a year.

It is very easy to talk about the production of clean milk, but a very different thing to get it to the market and to the public in a clean and safe condition. Being much interested in this problem, I decided in 1939 to try to produce clean milk myself, and learn at first hand the difficulties. With this object in view I built a model cow-shed, which has every facility for complete cleanliness, and which is cleaned throughout twice a day and washed out with disinfectant weekly. I then imported from Guernsey, where there is no tuberculosis among the cattle, cows which had passed the tuberculin tests, and also the agglutination tests for *Brucella abortus*.

Every conceivable care with regard to clean milking has been scrupulously carried out, including regular washing of udders and teats with disinfectants, clipping of udders, tying of tails, washing and disinfecting milkers' hands between each cow, etc. The milk is cooled immediately each cow is milked, and all utensils washed, scrubbed, and sterilized twice daily. In spite of every precaution *Brucella abortus* infection broke out among my cattle. How this can be avoided I do not know. This disease is extremely prevalent among cows, and I feel it is quite probable that the infection may be brought to the pastures by birds. I do not believe that this disease can be easily prevented. The cows have been tested with tuberculin at regular intervals and there are no reactions. The milk, after it has left my dairy, has to be taken to a roadside spot, where it stands until it is collected by an open lorry, which travels round the neighbourhood and then takes it to a collecting depot, whence it is sent to London. During this transit, especially in the summer when the sun is shining on the churns, the milk must be warmed up again. It is collected about 10.30 a.m.

I have had bacteriological examinations of freshly drawn milk made by Dr. Fraser at the Bristol Royal Infirmary which are satisfactory, and of which the following is an example: "Plate culture at 37° C. 170 colonies in 1 c.cm.; plate culture at 20° C. no colonies in 1 c.cm.. No *B. coli* in 10 c.cm. The deposit shows a very rare leucocyte; no organisms seen. The bacteria present are scanty and chiefly *Staphylococcus albus*." But in spite of this and every precaution the mixed night and morning samples have not been satisfactory, the methylene-blue test has not been satisfied, and *B. coli* have been present in various analyses.

It is impossible in any cow-shed to prevent a certain amount of dust, carrying bacteria and floating in the air, which may easily contaminate the milk with *B. coli*, while flies in summer may be dangerous. It must be remembered that cows are by nature particularly unclean animals with their splashing excreta. The chief sanitary inspector of the county describes my quarters as excellent, and the dairy experts find no fault with technique. As the result of this experiment I am more than ever convinced that there is only one way to safeguard the community, which is to pasteurize the whole of the country's milk.—I am, etc.,

Churchill, Somerset. J. R. CHARLES.

Diphtheria during Immunization

SIR,—Dr. G. A. Garrett (Jan. 23, p. 102) described a case of a type which has great significance in any evaluation of diphtheria immunization. By referring to it as one of diphtheria, Dr. Garrett has assumed that a positive swab and a sore throat are synonymous with diphtheria. From his very concise account of the clinical evidence and the rapid response to anti-streptococcal chemotherapy it is quite clear that he was dealing with a case of follicular tonsillitis, and the positive K.L.B. swab was a coincidence of no pathological significance. Since immunization has been more extensively practised such a set of circumstances is not uncommon, as medical officers of health and isolation hospital superintendents well know.

Immunization protects against the disease and not against a positive swab, and, just as a typhoid carrier can contract enteritis from some other cause, there is no reason why a carrier of K.L.B. should not suffer from a streptococcal or other form of throat infection. If we are to gain anything like an accurate estimate of the effect of immunization on the *disease* diphtheria it is imperative that medical officers of health should carefully investigate every case, whether immunized or not, which is notified as diphtheria, particularly when the decision to notify rests on a positive swab. Since for all practical purposes all such cases are removed to isolation hospital this should not offer any undue difficulty.

The general practitioner, even if he doubts the diagnosis, quite rightly cannot ignore a positive swab, but that does not justify medical officers of health, who have the duty of making the returns to the Registrar-General, in systematically allowing all notifications to remain in their returns without question, and without subsequent deletion where further investigation would show that a positive swab report, probably on one occasion only, was completely at variance with all the clinical evidence. In the absence of such necessary precautions the Registrar-General's returns will continue more and more to give an erroneous impression of the influence, or lack of it, of immunization on diphtheria the disease.—I am, etc.,

F. LAWRENCE SMITH,
Carshalton. Medical Officer of Health

SIR,—Dr. G. A. Garrett (Jan. 23, p. 102) discusses the possibility of diphtheria arising during immunization as the result of a negative phase occurring after an injection of A.P.T. For the sake of brevity, I should like to draw his attention to the following points.

1. A negative phase following the injection of any antigen would certainly not last for nearly three weeks, in all probability not more than a few days. It is likely that the importance of the "negative phase" has been overstressed in the past.

2. There is no proof whatever that the case quoted was indeed diphtheria. A positive swab in the absence of definite clinical signs is not a safe criterion of diphtheria, especially as the organism was not typed or other tests for virulence carried out. Moreover, the state of the child's original immunity was unknown. Presumably Dr. Garrett was surprised at the result, as I can only assume the sentence "A negative swab was not anticipated" is an error.

3. Even were the case one of genuine diphtheria of a mild variety this would not be surprising, as the child would be

in exactly the same position to contract the disease as any other non-immunized susceptible child.

4. The statement that the knee-jerks are often absent in early diphtheria is a myth. Even in cases of hypertoxic diphtheria it is rare for the knee-jerks to be lost during the first week. Nor can any reliance be placed on such signs as the height of the temperature, presence or absence of albuminuria, etc., none of which is particularly diagnostic of diphtheria. The decision must be made on the appearance of the throat, and in doubtful cases on a knowledge of the patient's immunity as shown by the Schick test and the results of typing and virulence tests in the laboratory.

5. With regard to Dr. Garrett's comment, first of all there is no ground whatever for assuming that under any circumstances a non-virulent organism can become virulent.

6. If swabbing were resorted to before immunization the presence of virulent bacilli would show that immunization was in fact unnecessary as the patient would surely be Schick-negative, otherwise clinical diphtheria would have developed. In any case the administration of diphtheria antitoxin would not have the slightest effect on the carrier state.

7. Finally, the only advantage which might accrue from giving antitoxin with the immunizing agent would be to procure an immediate and remote immunity by Ramon's method, instead of waiting for active immunity to appear several weeks after the final injection.—I am, etc.,

Plymouth D. F. Johnstone.

Treatment of Ischaemic Contracture

Sir,—Your annotation (Jan. 23, p. 108) is fully warranted, but it is doubtful whether arteriectomy is primarily necessary. The application of contralateral heat, according to Learmonth's suggestion, is frequently sufficient to release the collateral circulation (*Surgery of Modern Warfare*, first edition, chap. 36, p. 317). I have used this method in three cases of threatened ischaemia, in cases of supracondylar fracture of the humerus in children, and in each of these it has been successful in averting the onset of contracture. (A fourth case where it was unsuccessful was found to have an incomplete lesion of the brachial artery.) The child was put into a bath with the injured limb suspended above water level, and the return of function was almost dramatic. I would earnestly recommend that this measure be tried before operative proceedings are undertaken. —I am, etc.,

Sunderland. W. Grant Waugh.

Mitral Systolic Murmurs

Sir,—I read Dr. William Evans's very useful article on mitral systolic murmurs (Jan. 2, p. 8) with great interest and profit. After discussing it with several colleagues, however, I got the impression that it perhaps lends itself to a little confusion. In using the word "irrelevant" one naturally feels that it should mean irrelevant to something or other, and in the terms of the article that something or other is not quite clear. It looks as if Dr. Evans is calling a murmur irrelevant at the mitral valve when it is heard better at some other valve, and not merely when the disease it signifies is in some other valve. The mitral murmur associated with pulmonary stenosis, for instance, is called irrelevant, while that which may be associated with aortic stenosis is not. Would it not be clearer to say outright that "irrelevant" means "irrelevant to disease at the mitral valve." The classification of mitral murmurs would then run as follows: (1) organic—(*a*) relevant, (*b*) irrelevant; (2) non-organic—i.e., innocent.

Accepting Dr. Evans's well-grounded view that mitral incompetence is not established as a pathological entity, the class of relevant mitral murmurs would then be reserved for those signifying mitral stenosis (of which the systolic would, in certain circumstances, be one). In the irrelevant class would fall all those murmurs signifying pathology elsewhere. According to this, the murmurs of pulmonary and aortic stenosis would be classed together, and in the innocent class would fall all those murmurs which could not rightly be identified with pathology anywhere. It would be possible, of course, to divide the irrelevant murmurs into those signifying pathology in the heart (but not in the mitral valve) and those signifying pathology outside the heart. But perhaps this would unnecessarily complicate the classification.

Dr. Evans's main point is that the mind of the clinician should be always correlating what he hears with some definite conception of pathology, or the absence of pathology, and for that reason it would seem desirable that the terms of his classification should relate directly to the site of pathology, if any. This would help to keep his mind on the point, and prevent him from admitting into his nomenclature hazy theories of disease which have never been concretely demonstrated.

Incidentally, Dr. Evans's insistence on the value of the clinical interpretation of heart murmurs will come as a welcome encouragement to those of us who have no gadgets at our command, and will inspire us to recapture some of the clinical acumen which is fast becoming a departed glory.—I am, etc.,

Liverpool C. H. Ross Carmichael.

Mass Miniature Radiography Units

Sir,—The letters of Dr. Norman P. Henderson (Jan. 16, p. 81) and Dr. James F. Brailsford (p. 83) raise several important points. While the battle for mass miniature radiography in the Services has been won, the battle for its use in the civil population is only in the preliminary skirmishing phase.

The situation appears to be that about a dozen units have been allotted to cities and another dozen are being distributed among certain counties. To those of us who have worked hard in preparing ourselves for service in this new method and in stimulating interest in local medical and lay circles, the fact that our district is not on the short list for a unit is discouraging. This feeling would quickly be dispelled by a little more information from the Ministry of Health in regard to its policy, with special reference to the expected dates of delivery of the units to the various centres. I believe it to be a fact that local authorities have recently received a memorandum from the Ministry on their proposed scheme for mass radiography, but the radiologists who will (or should) have much to do with the practical work are still much in the dark. Surely it would be helpful if each district could know soon approximately when it might expect to take its part in the national scheme, so that it could set about planning in earnest. No doubt all plans will have to be approved by the Ministry, and this takes time. It is to be hoped that the staffing of units will be delegated to regional authorities who are in the position to pick the best teams. In regions containing two or more large towns, each town, so far as is possible, should be represented by a team member.

Dr. Henderson makes the point that the real province of the "chest physician" is the clinical side of the examination, and suggests that it is a waste of time for him to examine large numbers of normal films. There is much truth in this, and yet the combination of radiologist and physician is better than either alone. That a number of physicians do not act on this principle is a matter for regret. There is a tendency for tuberculosis officers to request hospitals to supply chest films without reports, implying that they are quite competent to interpret them without assistance, and no doubt they are in the majority of cases. But do we not all frequently see films in which there is some point of difficulty or doubt? Do we not then welcome a discussion with a colleague? If, as so often happens, a discussion is impossible, surely the next best thing is to read our colleague's thoughts on paper. Many of the reports will be superfluous, but there will always be a few which contribute some piece of information that would otherwise be missed. I feel strongly that this argument justifies a radiologist's report in every chest case.

One last point in regard to staffing. Uniformity throughout the country in technique and in the classification of reports is essential for success. Cannot this best be achieved by setting up a central school which will train radiographers and organizers of units in a standard method and coach members of viewing teams in approved methods of viewing and classification? To those appalled by such a mechanical concept I would suggest that miniature mass radiography is a mechanical sieve and is not a medium for the art of diagnosis. Uniformity at this stage will not atrophy individual diagnostic skill, which is called for at a later stage. Dr. Brailsford thinks that "it is a defective sieve which will miss the early case." Surely it would be truer to say that it will miss some early cases, but it will find more than it misses. It will not be the fault of miniature mass radiography if suspicious lesions, unassociated with clinical signs, are allowed to spoil the life of a patient. The assessment of the importance of such a lesion rests with the clinician. The viewer who sees it first in a miniature film is not responsible for its interpretation.

I cannot agree with Dr. Brailsford that the revelation by mass radiography of extensive progressive tuberculous disease is to be regarded as a slur on the medical examination which missed it, for the adequate reason that many such cases have never had a medical examination.—I am, etc.,

Reading. PAUL CAVE.

Ligature of the Innominate Artery

SIR,—In reporting the end-result of a case of ligature of the innominate artery (May, 1932) for subclavian aneurysm in the *Journal* of Oct. 10, 1942 (p. 422), I mentioned 62 recorded cases and said that I was unable to obtain figures for recent years. Subsequently, my attention was called to three additional cases, all of them successful and noteworthy.

The first, a woman aged 65, was operated on by Mr. H. S. Meade of Dublin in November, 1936. The case was published under the title "Compression of an Aneurysm of the Innominate Artery with Fascial Straps" (*Irish J. med. Sci.*). This case was seen in 1942, completely cured. Mr. Charles MacAulay of Dublin operated on a second case—also a woman—in March, 1933. The artery was ligatured. She was shown at the Royal Academy of Medicine in Ireland in 1937, and in 1942 appeared to have made a complete recovery. The third case was reported by Mr. Granville Chapman of Grimsby (*Journal*, July 13, 1939). Mr. Chapman writes that the man is well and alive 14 years after operation.

I am anxious, if you can spare the space, to correct the omission in my original communication by calling attention to these three cases.—I am, etc.,

W. I. DE C. WHEELER.

Artificial Respiration

SIR,—Eve's method has a mechanical but no theoretical superiority over Schäfer's method. In Schäfer's method the operator acts against the force of gravity in the first movement. When he withdraws this force gravity causes the viscera to resume their former position. Only if the body were on a head-downwards incline could the viscera stay put and not resume their former position. The more placid and toneless they are the more vigorous will be the resumption caused by gravity.—I am, etc.,

Birmingham. W. J. BURNS SELKIRK.

Teaching First Aid

SIR,—Should not the teaching of first aid be divided into two distinct categories: (*a*) for the casualty services, founded on the St. John and B.R.C.S. manuals; (*b*) for part-time wardens, rescue parties, Home Guard, W.V.S.—in short, everybody—founded on half a dozen essentials? The reason for this division is that first aid is based on anatomy, physiology, and chemistry, recondite subjects on which the public has little knowledge.

The rules for treatment are, for those under instruction, a matter of memorizing rather than reasoning. This memorizing can only be achieved by constant repetition—a method employed by the casualty services with their weekly or fortnightly drills. This constant repetition is out of the question with wardens, Home Guard, etc., with their many other duties; therefore the rules of treatment have to be reduced to a minimum if they are to be remembered. Six things should be taught: (1) control of haemorrhage by direct pressure; (2) treatment of shock; (3) treatment of broken limbs when no splints are available; (4) how to lift a casualty; and two "don'ts"—(5) don't wash wounds; (6) don't use oil on burns.

A booklet on these lines (10 pp.) was issued by our A.R.P. department eighteen months ago. It improved the first aid of part-time personnel greatly. Should any reader be interested in the views expressed above a copy will be sent if application is made to the A.R.P. Office, Princes Street, Huntingdon.—I am, etc.,

ARTHUR S. G. BELL,
Surg. Commander, R.N. (ret.).

Huntingdon.

Obituary

SIR STCLAIR THOMSON, M.D., F.R.C.P., F.R.C.S.

Formerly Professor of Laryngology and Physician for Diseases of the Throat and Nose, King's College Hospital

Sir StClair Thomson, whose death occurred on Jan. 29, at the age of 83, achieved fame in every direction in which he bent his energies—as a specialist in diseases of the larynx, as the author of the "Laryngologists' Bible," as a fluent interpreter at international congresses, as a good host, and as a most accomplished speaker. He was the Nestor of British laryngology, almost the sole survivor of the school which had established this specialty on a firm scientific basis.

Although StClair Thomson was born at Londonderry in 1859, his father was an Argyllshire man from the village of Ardrishaig on Loch Gilp. The "StClair" in his son's name was from his maternal grandfather, John Sinclair of the Sound of Mull. When he was 19 StClair Thomson entered as a junior scholar in the medical division of King's College, London. He took the M.R.C.S. and L.S.A. in 1881, and at the M.B. London examination in 1883 he obtained honours in medicine. He then became house-surgeon at King's College Hospital, where his chief was Joseph Lister, who had entered that hospital as a surgeon on the same day that Thomson had entered it as a student. StClair Thomson was never tired of recalling his great master. Fifty-six years after the event, in the rooms of the Medical Society of London in Chandos Street, Cavendish Square, he described the scene in those very rooms in 1883, when he had the honour of bringing together and exhibiting with Lister the first six cases in which a fractured patella had been wired.

StClair Thomson completed his training in Vienna, Paris, and Lausanne, making acquaintance with foreign surgeons and their methods and establishing his knowledge of laryngology. At King's College Hospital at the time he was a student the teaching in this subject was wholly inadequate. He once said that when he gained his degree in medicine he had never seen the vocal cords—or the drum of the ear—in the living person. He also recalled how, when it was necessary to operate for adenoids in the out-patient department in the 'eighties, the struggling child was held by the porter, while the surgeon, whose only instrument was his finger-nail, inserted his finger up behind the palate and scratched out as much of the adenoids as the yelling child would permit.

In Vienna one of his great teachers was Hajek, afterwards professor of laryngology and rhinology at the University there, but then a privat-docent. One of StClair Thomson's possessions which he exhibited proudly half a century later was his postgraduate notes on Hajek's lectures on the anatomy of the nose and throat. It was Hajek who taught him the importance not only of looking at specimens but of handling them and making his own sections. Thomson also worked in Vienna with von Schrötter, Stoerk, and Politzer. In his old age Hajek fell a victim to Nazi persecution and became an exile in this country, and it was the pleasure of StClair Thomson to repay as far as he could the old debt to his teacher by welcoming and acclaiming him in laryngological circles in London.

During his wanderings abroad in his early manhood, which included some experience of practice in Italy and Switzerland, StClair Thomson not only laid the foundation of his knowledge and skill as a laryngologist but also acquired that polished cosmopolitanism which became him so well to the very end of his life. He loved to talk of his time in Vienna, in particular of the long summer of 1893 when the Redehöf (not now to be discovered in the Austrian capital, but commemorated in the operetta *Lilac Time*) was crowded with students and the life of the University was especially rich and inspiring.

Laryngology in London

In that same year (1893) he returned to London and took the F.R.C.S. He had already taken the London M.D. in 1888, and also the M.D. of Lausanne in 1891. He became physician to the Throat Hospital, Golden Square, and surgeon to the Royal Ear Hospital. In 1901 he was appointed assistant physician for diseases of the throat and nose at his old hospital, King's College, where his department had two beds in the male and two in the female surgical wards, but no special theatre, a room being fitted up for operations. In 1903 he was elected F.R.C.P. In 1905 he became physician in charge of the department, and in 1908 professor of laryngology at King's College. A few years later, in 1913, the hospital migrated from the byways of the Strand to the more open spaces of Denmark Hill. He continued to hold the two appointments until his retirement in 1924 at the age of 65, when he was made consulting surgeon and emeritus professor. His connexion with King's College, so long and distinguished, was further marked by his election to the Fellowship of the College in 1927, and by the unanimous choice of him for the chair of the past and present students' centenary celebrations in 1930.

An adequate estimate of the contributions of StClair Thomson to laryngology cannot even be attempted in the brief space of a memoir. One subject to which he devoted himself in particular was intrinsic cancer of the larynx. In the course of his experience he had seen that condition pass from being regarded as a most dire disease to one of the most amenable from a surgical standpoint, and he himself helped in a marked degree to bring about that change. Laryngofissure, from being an operation with a high mortality, was made safe by improvements in early diagnosis and technique, and this advance was due in large measure to his work. His technique in the operation for malignant disease of the larynx was followed in the schools of laryngology all over the world, as were his methods of after-care, in particular the use of the sitting position for the patient as soon as possible after the operation. In 1927 he exhibited at the Royal Society of Medicine four patients—all medical men—upon whom he had performed the operation of laryngofissure, respectively two and a quarter, three, four and a half, and five and a half years previously, for intrinsic epithelioma, and they were all, at the time he showed them, engaged actively in their practices. He held that if laryngofissure was carried out according to the correct technique it should be free from danger to life and should be followed by an adequate voice and lasting cure. In 1930, with Mr. Lionel Colledge as co-author, he published a book on this subject.

Tuberculosis of the larynx was also one of his great interests, and in a work from his pen in 1924 he described about 2,500 cases which he had seen during thirteen years while holding the appointment of visiting physician for diseases of the throat to the King Edward VII Sanatorium, Midhurst. In 1936 he was presented by the Royal College of Physicians with the Weber-Parkes prize for his work on tuberculosis carried out over a long period. His work as a surgeon was distinguished by the utmost care in examination, courage in undertaking surgical procedures, well-thought-out methods of after-care, and punctilious recording and description. It was he who published the first recorded case in this country, in 1910, of the removal with the aid of endoscopy of a foreign body—a shawl pin—which had been impacted in the secondary bronchus.

His famous textbook, *Diseases of the Nose and Throat*, first appeared in 1911, a second edition in 1916, a third in 1926, and a fourth, in which he was assisted by Mr. V. E. Negus, in 1937. He contributed innumerable papers to the medical journals and societies, and was the European editor of the *Laryngoscope*. His first publication was in 1895—a translation of Ónodi's *Anatomy of the Nasal Cavity*. Among appointments other than those already mentioned which he held at various times were those of surgeon to the throat and ear department of the Dreadnought Hospital, Greenwich, professor of laryngology and otology at the Royal Army Medical College, consulting throat physician to the Actors' and Music Hall Artistes' Associations, and physician to the Royal Italian Opera.

In 1913, when the International Medical Congress was held in London, Sir StClair Thomson—he had received his knighthood in the previous year—was president of the Section of Laryngology, and his command of languages enabled him to welcome each national group of delegates in its own. In 1918 he was president of the Medical Society of London, and in 1924-6 president of the Royal Society of Medicine. It was through his generosity that that society, shortly after he had relinquished the presidency, was granted an Achievement of Arms, and he also presented it with a presidential badge and chain of office, the badge consisting of the shield of the coat of arms encircled by the motto of the society—*Non est vivere sed valere vita.*

StClair Thomson was a corresponding honorary member of most of the laryngological societies of Europe and of the American Laryngological Association. In 1936 the Académie de Médecine of Paris unanimously promoted him, already a Foreign Correspondent, to be a Foreign Associate. Among other noteworthy decorations which he was entitled to wear were the swords of a Commander of the Order of Leopold, the ribbon of an Officer of the Legion of Honour, and the medal of the Reconnaissance Française. On the occasion of the visit of the British Medical Association to Canada in 1930, when he was president of the Section of Laryngology, he received at the Convocation of the University of Manitoba the honorary degree of LL.D. He was president of the same Section at Belfast in 1909 and at the Centenary Meeting in London in 1932. A recognition which perhaps pleased him most of all was the gift from 175 of his fellow laryngologists of a loving cup, which was presented to him in 1926. On that occasion he said that he had had two ambitions—one to till to the best of his ability the small corner of the field of medicine in which he worked; the other to accomplish it in such a way as to keep the esteem and regard, and if possible the affection, of his fellow workers.

Sir StClair Thomson was a widower, his wife, whom he had married in 1900, having died in 1905.

Mr. LIONEL COLLEDGE writes:

The tragic and violent death of Sir StClair Thomson will fill a vast number of friends, pupils, and patients with dismay. It is curious that during the last few years he had made no attempt to conceal from his intimate friends a slightly morbid preoccupation with the end which he felt was approaching; though he might, indeed, have lived for many years, for his health was not bad for a man past 80 and his family is remarkable for its longevity. Yet he could not have had the slightest suspicion of the manner in which his life would be cut short, and it recalls the disaster to the Blue Train in which he was travelling to the Riviera some years ago. Prof. Bérard hastened to the scene of the accident near Lyons and offered accommodation in his clinic. This Sir StClair declined, but soon afterwards found that he was more seriously injured than he had at first supposed. By that time the clinic was full and he had to be content with a place in the *salle des blessés* in the *Hôtel-Dieu*. He gave a vivid description of his sojourn there, which accorded ill with a cat-like love of comfort and elegant living.

The art of living was for him a special study of which he was complete master, and was reflected in the appointments and conduct of his home in Wimpole Street, where he loved to entertain his friends and especially his professional brethren. A recent and sad picture of him, though happily not the last, was sitting in the inner hall of his dismantled house, disposing of the treasures in the home he loved so well and was to occupy no more through the misfortunes of war. His love of hospitality and the social graces did not prevent him from being a worker of more than ordinary industry, and he covered the whole field of his special work in his writings; but he was interested particularly in laryngeal tuberculosis. He had in this a personal interest as one who had in early middle life made a remarkable recovery, which he attributed to the skill and care of his friend Dr. Patrick Watson-Williams, and he always referred to this with gratitude. On this account, too, the Tuberculosis Society always retained his interest and sympathy. His Mitchell lecture on tuberculosis of the larynx and his writing on the same subject for the Medical Research Council based on his work at King Edward VII Sanatorium at Midhurst show how careful a clinician he was and how thoroughly his cases were studied and followed. In this as in other things he preferred quality to quantity. The particular interest in the larynx naturally led to an intensive study of laryngeal cancer, where the same minute attention to every detail was invoked, and he became the acknowledged clinical authority on the subject. In the operations that he undertook the same qualities—which he had acquired from Lister, who exercised a direct and lifelong influence over him—were displayed, but he never undertook anything which he felt was beyond his powers, and was willing to hand over his cases without the least jealousy or rancour to those upon whom he believed that he could rely. His writings upon these subjects gained him an international reputation, but his enormous influence was exercised far more by his personality, which gained him the friendship of all the leading Continental and American laryngologists, and by his command of the spoken word, and that, too, in several languages. Whether it was after dinner, at a professional meeting, or at a Christmas party at his house, he always spoke with the same felicity and held the attention of his audience with a speech generally pointed with a quotation from his favourite Shakespeare. This combination of professional, oratorical, literary, and social ability would have led him to distinction in any line of life, and had he followed some other path he would have held first place at Canterbury, Westminster, or the Mansion House, and it is easy to picture him as an Ambassador.

That he had countless friends followed naturally, but he used to say that those friendships were the deepest and most enduring which came to him in the course of his work, and so by those who worked with him and reaped the benefit of his courteous instruction, his kindness, and his knowledge he will be remembered as the friend of laryngologists.

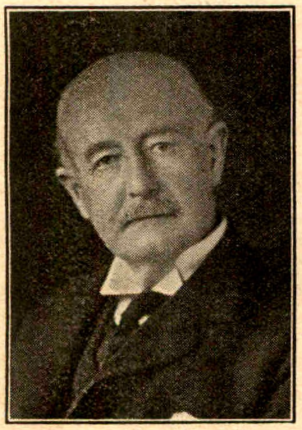
Mr. McADAM ECCLES writes:

Sir StClair Thomson from the very first took the greatest interest in the University of London Medical Graduates Society, for it was in his house in Wimpole Street it was born on Oct. 31, 1927. He became its first president, and presided at the inaugural dinner on Feb. 13, 1928, at the Langham Hotel. The society has gone on from strength to strength because of his wise guidance and sound judgment, and has now a membership of over 600. His genial presence, graceful oratory, and loyal friendship will be greatly missed by all.

SIR ROBERT ARMSTRONG-JONES, C.B.E., M.D., F.R.C.P., F.R.C.S.

We regret to announce the death on Jan. 31 at the age of 85 of Sir Robert Armstrong-Jones, consulting physician in psychological medicine to St. Bartholomew's Hospital.

Robert Armstrong-Jones was born in 1859 at Ynyscynhaiarn, Caernarvonshire, the son of the Rev. Thomas Jones, a Congregationalist minister who had formerly belonged to the Church of England. Robert Armstrong-Jones was one of a family of ten, and he used to recall how as a young boy he walked three and a half miles daily to and from Portmadoc Grammar School, where he received a prize for being the most regular and constant attendant during a severe winter quarter in 1871. When he was 14 he moved to the University College of Wales at Aberystwyth, and from there to Grove Park School, Wrexham. He took the London Matriculation in 1875, and after having served six months' apprenticeship to a Dr. Robert Roberts at Portmadoc he entered St. Bartholomew's Hospital. At Bart's he was prosector in anatomy and gained the Wix Essay and Hichens Prize. He qualified L.S.A. in 1880, took the London M.B. in the same year, and proceeded to the M.D. in 1883. He took the F.R.C.S. in 1885, and in 1900 the M.R.C.P., being elected Fellow in 1907. In 1920 he was given the Honorary D.Sc. of Wales University.



[Press Portrait Bureau

Leaving Bart's in 1880, Armstrong-Jones was for two years junior medical officer to the Royal Earlswood Institution, and then for six years at the Colney Hatch Asylum. In 1888 he returned to Earlswood as medical superintendent. After six years' service in this capacity he was appointed in 1893 the first medical superintendent to the first new asylum of the London County Council at Claybury; at the same time Dr. (later Sir) Frederick Mott was appointed pathologist. Jones's energy, enthusiasm, tact, and administrative ability made the renown of Claybury as an institution spread far beyond the area controlled by the L.C.C. It was the first asylum under municipal control to receive private paying patients, and it is interesting to recall these words from the first annual report: "It is hoped that the success of this experiment may encourage the Council to provide further for a class of patients above the pauper class but who can ill afford to bear the cost of private asylum, and who may find comparative quiet and comfort—perhaps even a touch of 'home'—in such an institution as the Claybury mansion-house." Armstrong-Jones organized the teaching of mental nurses and instituted a special training course for them, and his work on behalf of mental nursing was recognized by the conferment upon him of Knight of Grace by the Order of St. John of Jerusalem. Whilst Armstrong-Jones was superintendent, Frederick Mott was at the same time working in the pathological laboratory and making his fundamental and well-known contributions to the pathology of insanity. Armstrong-Jones was for several years honorary general secretary to the Medico-Psychological Association, and later became its president. With F. E. Batten he was joint secretary of the Psychological Section of the International Congress on School Hygiene which met in London in 1907.

After nearly twenty-five years of arduous service at Claybury, he felt compelled by the stress and strain of administrative and medical work to resign his appointment in 1916; in the following year he received the honour of knighthood. After a short time of rest Armstrong-Jones offered his services to the War Office and was appointed first consulting physician in mental diseases to the London Command. He was also consulting physician to the American Red Cross Hospital at Alford House. His war services were recognized by the honour of C.B.E. (Military). After the war he was appointed to be one of the three Lord Chancellor's Visitors in Lunacy, an office he held for ten years. Later he was nominated Justice of the Peace and Deputy Lieutenant for the Counties of London and Caernarvon, and in 1929 he was High Sheriff of Caernarvonshire. Armstrong-Jones lectured in mental diseases both at St. Bartholomew's Hospital and at the Westminster Hospital, published a *Textbook of Mental and Sick Nursing*, and contributed articles on insanity to *Quain's Dictionary of Medicine* and to *Allbutt's System of Medicine*. He contributed articles to the general medical press and often vigorously expounded his views in the correspondence columns of the *Times*. In 1910 he was witness for the British Medical Association before the Royal Commission for Divorce and Matrimonial Causes, and served on a special Committee to Consider Spiritual Healing appointed by the Archbishop of Canterbury in 1920. In 1929 he delivered the Henderson Trust Lecture in the University of Edinburgh, the title of his lecture being "The Growth of the Mind." From 1917 to 1927 he was Gresham Professor of Physic.

Sir Robert Armstrong-Jones was actively interested in the affairs of the B.M.A.: he was secretary of the Section of Psychology at the Meeting at Newcastle-upon-Tyne in 1893, and president at the Swansea Meeting in 1903; in 1920 and in 1921 he was a member of the executive committee of the Kensington Division.

He married in 1893 Margaret Elizabeth, the elder daughter of Sir Owen Roberts, D.C.L.; they had one son and two daughters.

We regret to announce the death of Dr. ROBERT CRAIK of Ealing at the age of 77. Dr. Craik received his medical education at Glasgow University, qualifying M.B., C.M. there in 1886, and obtaining his M.D. in 1893. For many years he was medical superintendent of Conisborough Fever Hospital, Yorks, before going to Ealing in 1912. From time to time he contributed to the correspondence columns of the *Journal* on subjects in which he took a special interest, including the blood in lead poisoning and the blood picture 35 years after splenectomy. Dr. Craik's modest and retiring disposition kept him too much in the background, but his real worth was appreciated by all who came in contact with him. He had been a member of the B.M.A. for 20 years.

The Services

CASUALTIES IN THE MEDICAL SERVICES

We have recently received from Australia the annual report for 1942 of the Victorian Branch of the B.M.A. The following medical officers are included in the Roll of Honour printed in the report:

Died on Service.—Major E. Bailhache, Major J. F. Chambers, Lieut.-Col. E. L. Cooper, Capt. J. C. R. Joyce, Capt. G. L. Lindon, Major Z. Schwartz, Capt. D. J. Shale, and Capt. S. I. Weir, all A.A.M.C., and Fl. Lieut. S. Thomson, R.A.A.F. A brief obituary notice of Capt. Weir was published in the *Journal* of Sept. 6, 1941 (p. 361).

Major **Eric Bailhache** was educated at the University of Melbourne, where he graduated M.B., B.S. in 1924. He also took the M.R.C.O.G. in 1937. He died of wounds on Feb. 26, 1941. He had been a member of the B.M.A. since 1924.

Major **John Ferguson Chambers** graduated M.B., B.S. of the University of Melbourne in 1917, proceeding M.D. in 1925. He also took the M.R.C.P. in 1922. He was honorary physician with charge of in-patients at the Alfred Hospital, Melbourne, and honorary consulting physician to the Austin Hospital, Melbourne. He was killed in action in April, 1941. He had been a member of the B.M.A. since 1918.

Lieut.-Col. **Eric Leonard Cooper** graduated M.B., B.S. of the University of Melbourne in 1925, proceeding M.D. two years later. He was tutor in medicine at the Ormond College of the University of Melbourne and honorary physician to in-patients at St. Vincent's Hospital, Melbourne. He contributed articles to the *Medical Journal of Australia* on Hodgkin's disease (1934) and on athletics and the heart (1937). He joined the B.M.A. in 1925.

Capt. **John Colin Ramsay Joyce** took the M.B., B.S. of the University of Melbourne in 1926 and joined the B.M.A. in the same year.

Capt. **George Leonard Lindon** graduated M.B., B.S. of the University of Melbourne in 1940 and joined the B.M.A. in the following year.

Major **Zelman Schwartz** graduated M.B., B.S. of the University of Melbourne in 1920 and took the F.R.C.S.Ed. in 1924. He joined the B.M.A. in 1920.

Capt. **Donald James Shale** took the M.B., B.S. of the University of Melbourne in 1938.

Fl. Lieut. **Stuart Thomson** graduated M.B., B.S. of the University of Melbourne in 1937. He entered the R.A.A.F. soon after the outbreak of war and was killed in a flying accident. He joined the B.M.A. in 1940.

Believed to be Prisoners of War.—Major J. F. Akeroyd, Capt. B. H. Anderson, Major H. L. Andrews, Capt. V. Brand, Capt. V. G. Bristow, Major K. B. Burnside, Capt. J. F. J. Cade, Capt. F. J. Cahill, Major I. T. Cameron, Capt. J. P. Catchlove, Lieut.-Col. A. E. Coates, Major T. P. Crankshaw, Col. A. P. Derham, Major E. E. Dunlop, Lieut.-Col. N. M. Eadie, Major H. H. Eddey, Capt. J. L. Frew, Major R. B. Maynard, Capt. P. N. O'Donnell, Major R. G. Orr, Lieut.-Col. C. H. Osborn, Major H. A. Phillips, Col. D. C. Pigdon, Major J. J. Searby, Capt. H. N. Silverman, Lieut.-Col. H. F. Summons, Capt. H. F. Tucker, Capt. F. R. Vincent, Major H. A. W. Watson, Col. E. R. White, Lieut.-Col. J. G. G. White, Capt. M. F. A. Woodruff, all A.A.M.C.

Missing.—Capt. C. S. Donald, A.A.M.C., Surg. Cmdr. J. R. Hasker, R.A.N., Surg. Lieut.-Cmdr. F. H. Genge, R.A.N., Surg. Lieut. W. J. McLaren-Robinson, R.A.N., Capt. J. F. Park, A.A.M.C., Surg. Lieut.-Cmdr. E. M. Tymms, R.A.N.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

At a Congregation held on Jan. 22, 1943, the following medical degrees were conferred by proxy:

M.D.—H. H. Bayley, C. W. C. Karran.

M.B., B.Chir.—A. E. Howarth, A. D. Barlow, J. F. B. Carter, D. S. G. Genge, R. N. Jones, T. G. E. Loosemore, R. D. Slack, H. C. Still, J. K. F. Mason, W. N. Coombes, R. K. Reid, J. H. Simpson, R. N. Ticehurst, W. H. Trethowan, O. B. Appleyard, N. A. Campbell, J. A. H. Collyns, R. V. Peters, W. Rogers, M. C. Connell, P. H. N. Matthews, J. F. Neil, D. W. H. Griffiths, M. C. Mundle, B. P. Webber, J. H. C. Phillips, A. P. H. Randle, W. A. dos Santos, A. G. Harrold, A. G. Richards, P. F. Early, F. W. Blackley, E. F. Carr, W. K. Douglas, H. L. Pierce, H. R. Jolly, M. G. P. Stoker, B. C. Welshman. *In person:* H. W. A. Baron, J. V. T. Gostling.

The dissertation by M. J. Clow, M.B., B.Chir., has been approved for the degree of M.D. in absence.

UNIVERSITY OF LONDON

A course of lectures and clinical instruction on mental deficiency and allied conditions, arranged by the University Extension and Tutorial Classes Council in co-operation with the Central Association for Mental Welfare, will be given from Monday, May 10, to Friday, May 21, at the London School of Hygiene and Tropical Medicine, Keppel Street, W.C. It is intended for medical practitioners, more especially those who are engaged as school medical officers, certifying officers to local authorities under the Mental Deficiency Acts, or as medical officers of institutions. Detailed time-tables will be sent not later than May 3 to each person proposing to attend the course, and applications should be sent in by March 20 as the course can be held only if sufficient entries are received. The University will grant certificates of attendance to those students who attend regularly taking both theoretical and practical work. The registration fee, to be paid at the time of application, is 10s. 6d., and the fee for the course is £5 15s. 6d. All communications should be addressed to Miss Evelyn Fox, C.B.E., c/o University Extension Department, University of London, 24, Buckingham Palace Road, London, S.W.1.

UNIVERSITY OF EDINBURGH

At a graduation ceremonial on Jan. 21 the following medical degrees and diplomas were conferred:

M.D.—*J. W. Buchanan, Surg. Lieut., R.N.V.R., *R. F. Dawson, Squad. Ldr., R.A.F.V.R., *O. S. Gibbs, *N. S. Gordon, Flying Officer, R.A.F.V.R., *W. Limont, Surg. Lieut., R.N.V.R., J. A. F. Roberts (highly commended for thesis).

M.B., Ch.B.—P. H. L. Barker, G. T. Bedford, G. V. R. Born, M. A. Caldwell-Nichols, E. M. Callander, K. M. Chalmers, T. B. Chetty, D. H. Clark, *W. A. L. Collier, D. J. C. Cunningham, Helen W. Currie, K. J. R. Cuthbert, D. A. Dixon, W. Edgar, G. M. Falconer, E. C. Fear, Margaret M. Fleming, J. P. W. Grant, D. R. Gunn, K. Gunstensen, W. J. Howrie, D. W. Huish, W. H. Hunter, R. B. Huston, B. C. Jeffrey, D. R. Kerr, W. A. E. Kerr, A. D. M. King, R. P. T. King, W. T. Lesslie, D. W. Livingstone, D. G. M'Connell, A. C. Macdonald, Evelyn E. M'Guinness, Annie H. Mackay, L. M'Lachlan, A. S. ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW

Surg. Rear-Admiral Cecil P. G. Wakeley will deliver a lecture, under the auspices of the Dr. John Burns Fund, on "The Surgical Aspects of Blast" in the hall of the Faculty (242, St. Vincent Street, Glasgow) on Wednesday, Feb. 10, at 4 p.m.

Medical Notes in Parliament

The National Loaf

Mr. Mabane stated on Jan. 20 that, apart from yeast, salt, and the various improvers which are the recognized adjuncts of bread baking, the permitted ingredients of national flour for making the present national loaf are wheat flour of 85% extraction, imported white flour, oats products, barley, rye, milk powder, and calcium, in the proportions authorized. In addition the baker may use a proportion of white flour as permitted in Article 20 of the Flour Order, 1943, and potatoes and potato flour as permitted in the Bread (Control and Maximum Prices) Order, 1943. The composition of national flour and consequently of national bread is not, and will not, be standardized over the whole country. The proportion of diluents does not at present in general exceed 5%. There was no present intention of rationing bread.

Milk Pasteurization

Mr. David Adams asked on Jan. 20 whether, with a view to destroying pathogenic organisms in non-pasteurized milk, it was now intended that all milk for human consumption should be scientifically pasteurized. Mr. Mabane replied that the appropriate and practical steps which could be taken to secure the elimination of active tubercle organisms from liquid milk were at present under consideration with the Agricultural and Health Departments and other interests.

Medical Certificates

Mr. Ernest Brown said on Jan. 21 that he was aware of the complaints of doctors that they were overwhelmed with the signing of certificates. In many cases the granting of some exemption or privilege must depend on the physical condition of the applicant. The only suitable evidence of this was a medical certificate. He was grateful to the medical profession for the assistance they had given. He had been consulted both by the other Government Departments concerned and by the medical profession. He was always ready to discuss proposals for restricting, and if possible reducing, the number of purposes for which medical certificates were required.

Treatment of Syphilis under Regulation 33B

On Jan. 26 Dr. MORGAN asked the Attorney-General whether, in view of the risks inherent in the modern treatment of syphilis by drugs containing arsenic, he had considered the probability of action for damages or legal suits against the special practitioners in connexion with their work under the compulsory treatment powers of Regulation 33B, and the position if a breadwinner died or could prove permanent disability as the result of enforced treatment. Mr. ERNEST BROWN, who replied, said the construction of the Regulation was a matter for the courts and not for him to determine, but he did not think that a patient who was treated under the Regulation was in a different position as regards claims against the practitioner than a patient treated by a practitioner who had been consulted in the usual way.

Prisoners of War in Hong Kong

On Jan. 26 Mr. A. HENDERSON informed Sir William Davison that it was believed that the majority of the prisoners of war had been transferred from Hong Kong, but it was probable that some 2,000 British and Canadian as well as some Indian prisoners remained there. The International Red Cross Committee delegate reported favourably on the Hong Kong camps in Oct., 1942, but later information indicated a deterioration in the rations and considerable outbreaks of disease during last summer. It was understood that prisoners of war admitted to hospital received adequate nursing, but that medical treatment was hampered by a serious shortage of drugs and other medical requisites.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* there were during the week further falls in the incidence of measles 1,830, and diphtheria 77; the notifications of whooping-cough and acute pneumonia continued on the upgrade—by 202 and 103 respectively. An increase of 149 cases of scarlet fever was recorded; the notifications of dysentery were down by 23.

Scarlet fever tended to be more prevalent in most counties, especially in Middlesex 28, Yorks West Riding 27, London 24, and Glamorganshire 33 cases more. Lancashire, with 31 fewer notifications than in the preceding week, provided the only exception of note to the general trend.

The returns from the counties for diphtheria showed only slight changes from the totals of the previous week. The only substantial variations were a rise of 21 in Lancashire and a fall of 46 in Yorks West Riding.

The total notifications of whooping-cough were higher than in the previous week. The largest increases were in Lancashire 45, Staffordshire 28, London 26, and Somersetshire 20.

Although measles was down by 13% for the whole country, notifications rose in several counties, especially in Hampshire 70, Yorks North Riding 61, and Kent 51. The greatest decreases were those of Yorks West Riding 433, Durham 296, Lancashire 222, Lincolnshire 166, Derbyshire 142, and Staffordshire 106.

Half the total notifications of dysentery were from three counties: London 18, Essex 15, Lancashire 14. The epidemic of dysentery in Middlesbrough C.B. is apparently subsiding, only 4 cases being reported during the week; there are only 14 persons under hospital treatment.

In *Scotland* measles was down by 148 cases; notifications of acute primary pneumonia were up by 60 and of whooping-cough by 48. A suspected case of small-pox in a 3-year-old girl has been reported from Bridge of Allan. She has been removed to an Edinburgh institution after a period of observation in a Stirling hospital.

Typhus in Germany

A League of Nations report states that a large increase of typhus has occurred among the civilian population in Germany during the war. In 1939 no civilian case occurred, in 1940 there were 6, and in 1941 the total rose to 395. During the first five months of 1942 there were 3,674 cases. Germany ceased to issue returns in September.

Returns for the Week Ending January 23

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 2,203, whooping-cough 1,841, diphtheria 998, measles 11,827, acute pneumonia 1,404, cerebrospinal fever 92, dysentery 113, paratyphoid fever 1, typhoid 7. In the large towns 100 deaths were ascribed to influenza.

No. 2

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Jan. 16

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1943					1942 (Corresponding Week)

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Includes paratyphoid A and B for Northern Ireland.

‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Medical News

A paper on "Measures for the Control of Malaria in India" will be read by Sir S. Rickard Christophers, F.R.S., at the Royal Society of Arts, John Adam Street, Adelphi, W.C., to-day (Friday, Feb. 5) at 1.45 p.m.

A week-end course for medical practitioners on factory medical services and industrial diseases will be held at the London School of Hygiene on Feb. 27 and 28. The proceedings will be opened by Sir Wilfred Garrett, H.M. Chief Inspector of Factories, at 2 p.m. on Feb. 27; at 2.15 p.m. Dr. A. J. Amor will speak on "Industrial Diseases of the Lungs"; and at 4.15 p.m. Dr. W. D. Jenkins will give an address on "Skin Lesions arising from Coal Distillation." The programme for Feb. 28 is as follows: 10 15 a.m., Dr. M. W. Goldblatt, "The Investigation of Toxic Hazards"; 11.45 a.m., Dr. H. B. Trumper, "A Method of Assessment of Physical Requirements for Processes, with Reference to Routine Medical Examinations"; 2 15 p.m., Dr. A. H. Bennett, "Industrial Fracture"; 3.45 p.m., Dr. A. R. Martin, "Recent Work on Antiseptics." The fee for the course is £1 1s. (plus 2s. 6d. if lunch is required), and applications should reach the secretary of the school (Keppel Street, London, W.C.1) by Feb. 22.

The morning session of a meeting of the Royal Sanitary Institute, to be held at Leicester on Feb. 20, will be devoted to two papers, one on tuberculosis in wartime by Dr. J. C H. Mackenzie, and the other on the milk supply of the future by Mr. W. W. Baum and Mr. F. G. McHugh, respectively chief sanitary inspectors of the county and the city of Leicester. Visits arranged for the afternoon include an inspection of a high-temperature–short-time pasteurization plant. Further information may be obtained from the hon. local secretary, Dr. E K Macdonald, M O.H., Grey Friars, Leicester.

The British Film Institute is arranging a week-end conference from April 2 to 5 on the film in national life. The conference will be held at the University College of the South-West, Exeter, and will be concerned especially with the influence of the film on society, with particular reference to children and adolescents. It is hoped to show examples of apparatus used in connexion with the employment of optical aids for instructional purposes. It is understood that the fees for the week-end should not exceed 3½ guineas. Further inquiries should be addressed to the British Film Institute, 4, Great Russell Street, London, W.C.1.

Dr. Henry Warner Collins (Inner Temple) and Dr. John Walter Hulme (Middle Temple) were called to the Bar on Jan. 26.

A Swiss Paracelsus Society has recently been founded under the presidency of Prof. Linus Birchler. Its organ will be entitled *Nova Acta Paracelsica.*

According to an account in a Berlin newspaper last December, a man in Frankfurt was fined 50 marks for summoning a doctor to a patient without sufficient reason

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to The EDITOR, British Medical Journal, B.M A. House, Tavistock Square, London, W C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p m). Orders for copies of the *Journal* and subscriptions should be sent to the Secretary.

Telephone No—B.M.A. and *B.M.J.*: EUSTON 2111.

Telegraphic Addresses.—EDITOR, *Aitiology Westcent, London;* SECRETARY, *Medisecra Westcent, London.*

B M.A. Scottish Office: 7, Drumsheugh Gardens, Edinburgh.

QUERIES AND ANSWERS

Income Tax

Inquiries by Inspector

"Nosey" exercised "the very strictest economy as to living expenses" in the first year of the war and lent all the money possible for the war effort. The inspector of taxes, noticing that the professional account showed smaller drawings than usual for living expenses, asked for particulars of the private expenditure on food, clothing, holidays, etc. This information was given, but had the inspector a right to ask for it?

*** The legal rights of an inspector of taxes are very limited, and such inquiries are made not by virtue of any authority *he* has, but because the assessing commissioners may wish to know, and such particulars can normally be required on appeal. In the circumstances referred to above the inspector's action seems to suggest too much zeal on his part.

Retired Practitioner—New Appointment—Residential Expenses

"X" is a retired practitioner living at B. He contemplates accepting a whole-time appointment at C. He would (for personal reasons) have to maintain his establishment at B. What can he claim for the expense of maintaining himself at C ?

*** The income tax Acts do not provide for any such allowance, and "X" would be liable to account for tax on his full salary. A possible remedy would be for the appointment to be on a "living-in" basis, the result being to reduce the monetary emoluments and consequently the income tax liability.

LETTERS, NOTES, ETC.

Nasal Defence

Dr Octavia Lewin (London) writes: The nose is almost universally described as the organ of smell and classified among the special senses. Should not rhinology rather be dealt with as a special branch of physiology and recognized as the first in importance of Nature's many defence measures? The Ministry of Health has published alarming statistics telling of the ravages of the common cold and the losses that the war machine is suffering in consequence. The grave increase in the incidence of tuberculosis may well be ascribed to failure of the germicidal powers of the nasal apparatus. The nasal toilet, which alone can keep the nose fighting fit, is handicapped through lack of attention during the school years, and difficulties have been increased since coupons are called for when hankies are needed, as they form an essential part of our personal equipment in a civilized community

"British Pharmacopoeia" Amendments

The General Medical Council has amended the *British Pharmacopoeia, 1932,* as follows:

Extractum Cascarae Sagradae Siccum.—When this is prescribed or demanded an extract prepared according to the following formula may be dispensed or supplied: Mix 900 grammes of cascara sagrada, in coarse powder, with 4,000 millilitres of boiling water, and macerate the mixture during three hours. Then transfer it to a percolator, allow it to drain, and exhaust it by percolation, using boiling water as the menstruum and collecting about 5,000 millilitres of percolate. Evaporate the percolate to dryness, reduce the extract to a fine powder, and add sufficient starch, dried at 100° C., to make the product weigh 300 grammes. Mix the powders thoroughly and pass the extract through a fine sieve.

Ferri Sulphas Exsiccatus—The content of $FeSO_4$ is changed from "not less than 80%" to "not less than 77%."

Paraffinum Molle Album.—When white soft paraffin is prescribed, yellow soft paraffin may be dispensed, and may be used in place of white soft paraffin in making the preparations of the *B.P.*

The Chemist's Shop in Denmark

Dr. K. E. Barlow (Coventry) writes: It is too little known that there are countries which have dealt radically and adequately with the questions of self-medication. Having been fined by the Coventry panel committee for excessive prescribing, I inquired into the arrangements in Copenhagen when I was there in 1939 Danish chemists are forbidden to sell medicine without a prescription from a doctor. Manufacturing chemists have not only to disclose their formulas but also their costs. A medical board only allows the manufacture of proprietary remedies when the sale price bears a relation to cost which is thought to be just. It is noteworthy that the manufacture of amidopyrine has been prohibited in Denmark—that in consequence the incidence of agranulocytosis is negligible. The appearance of the chemist's shop is characteristic of the arrangements which govern its business. It contains a full pharmacopoeial range in neat bottles and little else. The chemist must live on the premises and must get up at night when required to dispense urgent medicines Finally, excessive prescribing is checked by calling upon the patient to pay a small proportion of the cost of drugs—a cost which the Government ensures is reasonable. In Denmark doctors are never fined for using the therapeutic resources which are available to them.

BRITISH MEDICAL JOURNAL

LONDON SATURDAY FEBRUARY 13 1943

LUNG TUMOURS IN MICE AND MAN

BY

J. ARGYLL CAMPBELL, M.D., D.Sc.

From the National Institute for Medical Research, London

(WITH SPECIAL PLATE)

As the result of more than ten years' experiments (Campbell, 1934-1942b) in which mice were exposed once an hour for six hours on five days of each week for a year to a moderate cloud of dust from various substances, enough data have now been obtained for some general statistical examination. It is possible to compare, with some confidence the results elucidated from statistics of human lung cancer (Kennaway and Kennaway, 1936; Turner and Grace, 1938; and others) with results obtained from the above prolonged dusting experiments with mice. Herein some comparison is made between mice and man: (1) as regards agents which increase the incidence of lung tumours; (2) as regards the morphology of the tumours; (3) as regards the time factor or influence of age; and (4) as regards the factors of susceptibility and heredity. Reference is also made to the influence of irritation, both chemical and mechanical.

Full details of the methods of investigation and of the sources and compositions of the various dusts have been given in the previous publications, and will not be repeated here. Also, full references to literature appeared in these earlier papers, and only key references will now be included. Since lung tumours are very rare in mice younger than 10 months, only older mice are considered. Usually about 80% of the control mice and about 75% of the experimental mice survive for 10 months or longer: as a rule all the mice were allowed to fulfil their allotted span of life. Further, only those experiments in which a visible deposit of dust was apparent in the lungs are at present under review. The experiments with gases and smokes are excluded.

Agents increasing the Incidence of Lung Tumours

The evidence of statistics for human lung cancer indicates that an abnormal liability to this disease has been observed among workers exposed to coal-gas and tar, those engaged in the preparation and sale of tobacco, metal grinders, engineers, foundry workers, silica workers, chromate workers, some workers with a nickel dust mixture, and Czechoslovak pitchblende miners, while a somewhat high incidence has been observed in those whose occupation exposes them especially to road dust; these latter include paviours, road sweepers, and drivers of horse-drawn and motor vehicles. The inorganic substances, therefore, which appear to be dangerous are radium, arsenic, a "nickel" dust mixture, chromates, iron, and silica. As regards the new carcinogenic agents, the benzpyrene of tar and tarred road dust is more than under suspicion, while this substance is also suspected of causing lung cancer in heavy smokers, being present in small quantity apparently in the tarry matter as the result of combustion of tobacco at high temperatures; some positive results have been obtained in experiments with animals with this tarry matter.

Many of the above substances have been tested on mice, and the significance of the results for various dusts is given in Table I, by means of the statistical ratio of the difference between the percentage incidences of lung tumours in the dusted mice and the control mice to the standard error of the difference (Table I, column 5); the meaning of this ratio is given briefly in column 6 of the same table. It will be observed that the statistical evidence in favour of the particular dust increasing the incidence of lung tumours is highly significant for a sample of tarred road dust (No. 1), for a sample of a similar dust with carbon monoxide present, and also for a dust mixture containing equal parts of silica, iron oxide, alumina, and calcium carbonate. The increase in incidence of lung tumours in the experimental mice is definitely significant also with a sample of iron oxide, a sample of Czechoslovak pitchblende dust (No. 2) containing a small quantity of radium and arsenic, a sample of tarred road dust from which the tar had been removed by benzene, and a second sample of tarred road dust (No. 2). Experiments in which the increase in incidence is on the borderline of significance include a diluted "nickel" dust mixture, a bituminous coal dust from the South Wales Coal Survey, and another sample of Czechoslovak pitchblende dust (No. 1) containing no arsenic and practically no radium. Experiments in which the increase in incidence might have been due to chance include those with an exhaust soot, those with

TABLE I.—*Significance of Increase in Incidence of Lung Tumours in Dusted Mice*

Ratio (R) Numerical Order	Experiment	Percentage Lung Tumour Incidence		Ratio of Difference between E and C to Standard Error of Difference (R)	Significance of Increase due to Dust
		Dusted Mice (E)	Control Mice (C)		
1	Tarred road dust (1)	74·0	8·0	7·2	Highly significant
2	CO+tarred road dust	47·3	7·5	4·1	
3	$Al_2O_3+SiO_2+Fe_2O_3+CaCO_3$	19·4	0·0	3·6	
4	Fe_2O_3	32·7	9·6	2·9	Definitely significant
5	Czechoslovak dust (2)	20·3	2·1	2·8	
6	Tar-free road dust	44·8	20·0	2·7	
7	Tarred road dust (2)	13·1	1·4	2·6	
8a	Diluted "nickel" dust	29·8	12·5	2·2	Some significance, but near borderline
8b	Czechoslovak dust (1)	11·5	1·7	2·2	
10	Bituminous coal	12·1	1·9	2·1	
11	SiO_2+"nickel" dust	17·4	5·0	1·8	An increase, but might easily be due to chance
12a	$SiO_2+Fe_2O_3$	19·4	9·6	1·5	
12b	Carbon, exhaust soot	33·3	20·0	1·5	
14	$Al_2O_3+SiO_2+Fe_2O_3$	15·8	9·2	1·1	
15	Steel grindings	13·6	7·7	1·0	
16	Anthracite coal	9·1	7·0	0·4	No increase of any significance
17	Coal soot	20·0	20·0	0·0	

steel grindings, and various experiments with silica and iron. Finally, no material difference in incidence was observed in experiments with an anthracite coal dust from the South Wales Coal Survey and a coal soot from a chimney.

When the value of the ratio in column 5 of Table I is 2 it means that such a difference in tumour incidence would arise by chance only once in 20 trials; if the ratio is 2.5 the difference would arise by chance only once in 80 trials, and if 3, only once in 370 trials. For higher values, of course, the risk is very much smaller still. In all the experiments there were about 50 to 60 mice in both the dusted and control groups—that is, 100 to 120 in all. If the same percentage differences between dusted and control mice were to occur with higher numbers of mice they would be of much greater significance. It is thus possible to obtain further evidence that silica and iron increase the incidence of lung tumours by adding all the results together for any of the experiments in which silica and iron were employed. This has been done in Table II, from which it will be seen that of 346 control mice 7.8% possessed lung tumour, while the incidence among 475 mice exposed to various dusts containing either silica or iron, or both, was 20.1%. The value of the above statistical ratio from these percentages is 5.2, which indicates that the difference due to the dusting is highly significant. It is likely also that the cause of the increase in incidence of lung tumours in the mice exposed to the road dust with the tar removed (Table I) is also concerned with the iron and silica it contained, as is the increase in the case of the sample of Czechoslovak pitchblende dust (No. 1) which did not contain arsenic or radium.

TABLE II.—*Lung Tumours in Mice in Fe_2O_3 and SiO_2 Experiments*

Experiment	No. of Mice Alive		Animals with Lung Tumours					
	Control	Experiment	Control			Experiment		
			Total	Simple	Malignant	Total	Simple	Malignant

Bituminous coal	,, ,,	1	1	2	7	4	12	10	22	59	79%
SiO_2+"nickel" dust	,, ,,	7	17	4	3	0	0	0	0	31	26%

From the above results it is obvious that so far as many of the causes of the increase in incidence of lung tumours are concerned mice and man show very fair agreement. It is considered that the processes involved are of a prolonged chemical nature—that is, small quantities of the dusts go into solution in the tissues before producing the cancerous effect, possibly the end-result being the same with all the different substances. In most cases the dusting was of a moderate degree or less, so that only moderate deposits or less of dust were present in the lung tissue. Heavier dusting with the apparently inactive dusts might have produced more positive effects. This brings us to the consideration of the mechanical factor due to such deposits. The lungs of the control mice, of course, equally with those of the experimental mice, contain small quantities of dusts from the sawdust of their bedding, from their food, and from their surroundings in general; these dusts may exert some influence in the development of lung tumours in susceptible mice, which may explain their presence in the control mice.

Mechanical Irritation

It is possible, of course, that the masses or collections of dust in the lung tissue might cause irritation by mechanical pressure, particularly during the movements of respiration. The harder the dust, or the larger the masses, the greater would be the irritation. Also the clumps of dust might by pressure occlude blood vessels so that a local anoxia might occur, and evidence has been obtained of some influence of anoxia in increasing the incidence of lung tumours in mice (Campbell, 1940a). In addition iron compounds might be freed from any stationary blood or haemoglobin in the occluded capillaries, and a chemical effect of the iron might be thus set up indirectly.

To study more closely any influence of mechanical irritation or pressure it is necessary to have some quantitative method for measuring the experimental dust deposits in the lungs. This is possible with the coloured dusts, and also for colourless dusts if mixed with coloured dusts. From experiments with coal dust and silica it is apparent that the two dusts are ingested by the same cells, so that the extent of the coloured coal-dust deposits covers also that of the colourless silica, as proved by the distribution of the coal and fibrous tissue in the silica nodules in the mouse's tracheo-bronchial lymph nodes. With the aid of the microscope it has been possible to identify four main degrees of deposit, such as slight, moderate, heavy, and very heavy, with four intermediate degrees as indicated in Table III. A very heavy deposit indicates masses of dust which fill up about three-quarters of the lung tissue but do not appear to shorten to any extent the life of the stronger mice. Such a very heavy deposit is arbitrarily termed a 100% deposit. A moderate deposit is half this degree, or a 50% deposit. A very slight deposit indicates scattered specks and particles of the dust. In this way it has been possible to obtain eight degrees of deposit and to estimate by microscopical examination how many mice fall into each of these eight sections. These are all added together to get the total number of mice with dust deposits. Then an average degree of dust deposit for this total is easily calculated from the number and percentage deposit in each of the eight sections. This average is given in the last column of Table III, and by using these averages the degree of deposit in the various experiments may be compared. The same method is employed for the dust deposits in the tracheo-bronchial lymph nodes as shown for some of the dusts in the same table. All the experiments have been dealt with in this way, and the results are collected together in Table IV, which also records the state of the lymph tissue in the lungs and lymph nodes.

The dusts produced hypertrophy of the lymph tissue in many of the mice. Normally there are very few and scattered collections of lymphocytes near the blood vessels and bronchial tubes in the mouse lung tissue; any definite increase on this is regarded as hypertrophy or reticulosis. Such a hypertrophy occasionally occurs in control mice too, so that it is necessary to divide the percentage of dusted mice with such a condition by the percentage of control mice which also show a hypertrophy. This ratio is given in column 4, Table IV, and indicates the increase in lung lymph tissue due to the dusting.

TABLE IV.—*Average Dust Deposit and Increase of Lymph Tissue in Lungs and Tracheo-bronchial Lymph Nodes*

Lung Dust Deposit Order	Experiment	Lungs: Dust Deposit (%)	Lungs: Lymph Tissue Increase — Dusted Mice % / Control Mice %	Lymph Nodes: Dust Deposit (%)	Lymph Nodes: Lymph Tissue Increase — Dusted Mice % / Control Mice %
1	Bituminous coal	76	9·6	79	4·4
2	Tar-free road dust	60	—	66	—
3	Fe_2O_3	59	2·8	45	3·7
4	Carbon, exhaust soot	53	—	47	—
5	Steel grindings	51	6·2	40	2·3
6a	$Al_2O_3+SiO_2+Fe_2O_3+CaCO_3$	46	15·6 / 0 0	30	4 4
6b	CO+tarred road dust	46	—	—	—
8	Anthracite coal	45	6·1	47	1·8
9a	Tarred road dust (1)	42	—	—	—
9b	Tarred road dust (2)	42	2·0	66	2·8
11	Coal soot	41	—	38	—
12	Dil. "nickel" dust	40	3·1	41	4·3
13a	$SiO_2+Fe_2O_3$	38	2·7	27	2·7
13b	$Al_2O_3+SiO_2+Fe_2O_3$	38	17·1	25	2·7
15	Czechoslovak dust (2)	35	2·9	62	2·5
16	SiO_2+"nickel" dust	28	4·8	26	2·2
17	Czechoslovak dust (1)	21	1·0	31	2·4

Normally the tracheo-bronchial lymph nodes are two in number, and if the diameter is more than 2 mm. a hypertrophy is regarded as being present. The increase due to the dusting is shown in the last column of Table IV. This increase in the lymph tissue in the lungs and nodes due to the dusting may not only be an effect of mechanical irritation but also a chemical effect. There does not seem to be any very close agreement between the degree of dust deposit and the increase in lymph tissue. There are high increases of lymph tissue in the lung with the highest degree of dust deposit—that is, with the bituminous dust, and also with the dust mixtures containing alumina, which is very hard (Nos. 6a and 13b, Table IV). The hard steel grindings also produced a high increase in lymph tissue in the lungs (No. 5), as did the hard anthracite coal (No. 8). It is obvious that all the dusts increase the lymph tissue in the lungs and lymph nodes, which might indicate in general a mechanical effect. When iron was present many of the "lymph" cells in the lung appeared to be of a sarcomatous type and tended to spread out into the lung tissue; this is apparently a chemical effect (see Plate, Fig. 2).

TABLE V.—*Absence of General Dependence of Lung Tumour Incidences in Dusted Mice upon Heavier Degrees of Dust Deposit in Lungs*

Degree of Lung Dust Deposit Column 3. Order	Experiment	Total Mice with Deposits classified as "Moderate to Heavy" or Higher (%)	Lung Tumour Incidence: Dusted Mice (E) %	Dusted Mice (E) % for Group	Control Mice (C) %	Control Mice (C) % for Group	E/C Group
1	Bituminous coal	83	12·1	25·8	1·9	9·8	2·6
2	Tar-free road dust	60	44·8		20·0		
3	Fe_2O_3	54	32·7		9·6		
4	Steel grindings	40	13·6		7·7		
5	Carbon, exhaust soot	35	33·3	18·7	20·0	7·1	2·6
6	Anthracite coal	25	9·1		7·0		
7	$Al_2O_3+SiO_2+Fe_2O_3+CaCO_3$	18	19·4		0 0		
8	Tarred road dust (2)	16	13·1		1·4		
9	Coal soot	11	20·0	40·4	20·0	9·4	4 3
10	CO+tarred road dust	10	47·3		7·5		
11	Czechoslovak dust (2)	8	20·3		2·1		
12	Tarred road dust (1)	7	74·0		8·0		
13a	$SiO_2+Fe_2O_3$	2	19·4	18·8	9·6	7·6	2·5
13b	$Al_2O_3+SiO_2+Fe_2O_3$	2	15·8		9·2		
13c	Dil. "nickel" dust	2	29·8		12·5		
16a	SiO_2+"nickel" dust	0	17 4		5·0		
16b	Czechoslovak dust (1)	0	11·5		1·7		

As regards the influence of the dust deposits upon the incidence of lung tumours, it is perhaps better to consider only the heavier degrees of deposit, such as those termed "moderate to heavy" or heavier, since if mechanical irritation of the dust is a factor in production of lung tumours the heavier dust deposits should be more active than the lighter deposits. Therefore, in Table V the experiments have been arranged in the order of the percentages of the total mice with dust deposits heavier than a moderate degree. The only experiments in which half the mice or more had such heavy deposits were those with bituminous coal, tar-free road dust, and iron oxide. In column 4, Table V, the lung tumour incidences in the dusted mice (E) are given, and a glance shows that in general there is no correspondence with the numerical order of the mice which had heavy dust deposits, so that the heavier degrees of dusting in the main do not control the production of lung tumours. In order to make the comparison accurate it is necessary to consider at the same time also the incidence of lung tumours in the corresponding control groups of mice. This is shown in Table V. From the last column it is evident that all the experiments, when grouped in fours for convenience and clarity, show increases in the incidence of tumours irrespective of the numerical order for the percentages of mice with the heavier dust deposits. It may be concluded, therefore, that in general the increase in incidence of primary lung tumours caused by dusts is a chemical and not a mechanical effect; but it is not possible at present to exclude completely a mechanical factor, since the bituminous coal, tar-free road dust, and iron oxide, with the highest degrees of dust deposit, did produce increases in incidence of lung tumours of some statistical significance. There are cases of lung cancer among coal-miners, but the incidence is low compared with that for certain other industries. In the mouse experiments, too, the bituminous coal does not occupy a very high postion (Table I) as a stimulator of lung tumours, although the dust deposit in the lung in this case was the heaviest of all in degree. This bituminous coal and the anthracite coal were obtained through the courtesy of the South Wales Coal Survey Committee, on the suggestion of Dr. P. D'Arcy Hart. The results given herein are merely some preliminary results, the main experiments, undertaken for another purpose, not yet being completed. In the present experiment with anthracite coal the average degree of dust deposit in the lung was less than moderate (Table IV). In the unfinished experiments heavier deposits are expected.

Influence of Age and Sex

The large majority of deaths from human lung cancer occur after the age of 55—that is, in the closing years of life. In mice also, lung tumours are rare until the last quarter of their average existence. These facts indicate the importance of the time factor and point towards some very prolonged action. This is why the prolonged dusting experiments with mice have been persevered with. It is possible by means of intravenous injection of very small quantities of some new carcinogenic agents to produce lung tumours rapidly in certain strains of mice (Andervont and Shimkin, 1940). It is doubtful whether with such rapid action these results can be applied to the usual cases, in which such prolonged action seems necessary, unless it be assumed that under normal conditions inhibitory agents may also be present, as seems to be the case in some strains of mice whose lungs are very resistant even to intravenous injection of powerful carcinogens (Heston, 1942).

Although in mice and man the incidence of lung tumours is highest in the closing years of life, it might be argued that the resemblance is superficial, because a mouse lives only two or three years. In reply it may be stated that the rate of respiration is higher in the mouse than in man, and all metabolic processes seem speeded up in these small animals. At any rate, in both mice and man a relatively prolonged action of the dust seems necessary for the production of lung tumours under ordinary conditions.

In human lung cancer, males appear to be affected much more often than females, but some observers find that for simple adenoma the reverse is the case. With mice, on the whole, sex does not appear to play any great part, but in the case of the experiments both male and female mice were exposed equally to the adverse conditions. In man environmental conditions are usually different for the two sexes for a great part of the day. The entry of women into industry during the war may in time change the distribution of human lung cancer.

Influence of Heredity and Susceptibility

The milk factor recently discovered by Bittner to be so important for the development of mammary tumours in mice has apparently no influence on the incidence of lung tumours; but it is evident that by inbreeding with brother-to-sister matings it is possible to produce strains of mice either very susceptible or very resistant to development of lung tumours (Strong, 1936; Bittner, 1939; Murray, 1934; Little *et al.*, 1939; Furth *et al.*, 1933, 1941). In this respect heredity is important, and in man there is a suspicion that some such inbreeding has had an influence in the production of the high incidence of lung cancer in the Czechoslovak pitchblende miners, although the radium, arsenic, or some other inorganic substance may act as the trigger in the mechanism of its development. These substances, however, do not appear to be so active in similar miners in other places, so that heredity due to a certain amount of inbreeding in the case of the Czechoslovak miners may explain the difference. Even with this mechanism the cancers often appear only long after the miners have left the mines, so that the time factor is of great importance here too. In this Czechoslovak region there are also cases among men who have never been in the mines and have worked outside them altogether, which seems to point to an influence of heredity or some factor present in the outside dust as well as in the mine dust.

LEGENDS FOR SPECIAL PLATE

Magnification in all cases × 200

FIG. 1A.—White mouse, male, aged about 22 months; exposed to bituminous coal dust for 1 year. Part of edge of lung cancer with oatlike cells (early stage) advancing on walls of adjacent alveoli. Weigert, van Gieson.

FIG. 1B.—Metastasis, in tracheo-bronchial lymph nodes, of large oatlike cells from a similar part of lung tumour, another part of which is shown in Fig. 1A. Weigert, van Gieson.

FIG. 2.—Fawn mouse, female, aged about 27 months; exposed to dust mixture $Al_2O_3+SiO_2+Fe_2O_3$ for 1 year. Small oatlike and sarcomatous cells (mostly transverse section) in part of adenocarcinoma. Haematoxylin, eosin.

FIG. 3.—White mouse, female, aged about 21 months; exposed for 1 year to a diluted Czechoslovak pitchblende dust (2), containing some inorganic substances, including radium, arsenic, silica, and iron. Lung cancer cells with formation also of fibrous tissue. Haematoxylin, eosin.

FIG 4.—White mouse, male, aged about 29 months; exposed for 1 year to a diluted Czechoslovak pitchblende dust (1) without arsenic and radium. Transitional area from papillo-adenocarcinoma to oatlike and spindle cells. Haematoxylin, eosin.

FIG. 5.—Fawn and white mouse, female, aged about 21 months; exposed for 1 year to road dust minus tar. Part of lung cancer with various types and conditions of cancer cells. Haematoxylin, eosin.

FIG. 6A.—White mouse, female, aged about 21 months; exposed for 1 year to Fe_2O_3 dust. Primary lung cancer, papillomatous nature. Haematoxylin, eosin.

FIG. 6B.—Metastasis, in tracheo-bronchial lymph nodes, of glandlike cells from lung cancer in Fig. 6A. Haematoxylin, eosin.

FIG. 7B.—Metastasis near oesophageal wall (note muscle coat) from lung cancer in Fig. 7A. Haematoxylin, eosin.

FIG. 8A.—Chocolate mouse, male, aged about 25 months; exposed to a mixture of SiO_2+a nickel dust mixture for 1 year. Lung cancer with spindle and other cells. Weigert, van Gieson.

FIG. 8B.—Metastasis in tracheo-bronchial lymph node of oatlike cells from lung cancer in Fig. 8A. Some remains of lymph cells are seen in top right-hand corner. Weigert, van Gieson.

In the above mechanism of heredity genes presumably would be active. Nucleoprotein, it is said, forms part of the constitution of genes, and it appears that the same holds good for at least some viruses (Stanley and Knight, 1941). It is tempting to suggest that some link or chain in nucleoprotein may provide the bridge between the heredity theory and the so-called virus theory held by some observers for cancer in general. So far there is no evidence that a virus is concerned in lung tumour development, unless a virus is similar to a gene.

As a rule human populations, compared with closely inbred mice, are of very mixed strains, so that in man any influence of heredity must be much thinned out and scattered about, as it is in mixed strains of mice such as those used in the present experiments (Campbell, 1942b). Owing to this thinning-out of susceptibility in mixed strains, relatively large numbers of mice are required for each experiment. Human statistics in such a condition can hardly help in the solution of the problem unless it is realized that, as in the mouse, the mechanisms of development may be manifold and complex. Thus a very susceptible individual living in a moderately dusty atmosphere might be affected while an insensitive individual in a similar but very much dustier atmosphere might escape. It is this problem of susceptibility that at present interferes with the complete elucidation of the mechanism of lung tumour development. Although it is possible to name some factors which increase the incidence of lung tumours in mice and man, the ultimate *fons et origo* of the tumour itself remains obscure. Nevertheless it is obvious that dusts suspected or proved to be dangerous should be reduced as much as possible in industry and elsewhere.

Morphology of Lung Tumours

Many types of tumour cells are represented in the mouse lung tumours obtained in these experiments. There are simple adenomas, and very malignant tumours with extensions into other organs. Eighteen cases of such extensions into other organs have now been obtained among the experimental mice and only two such cases among the control groups. The most common extension is into the tracheo-bronchial lymph nodes, but extensions have been observed also in the heart, chest wall, and kidney. The tumours seem to arise often in collapsed areas of the lung, usually near the pleura; the cells become more or less cubical, and it is not possible to decide whether these cells arise from cells of the alveoli or as extensions from the terminal bronchioles. Many types of malignant cells may be found in one and the same mouse tumour, with transitions from the usual cells seen in adenocarcinoma to spindle-like cells or the larger and smaller oat cells, or to sarcoma-like cells. Some illustrations of these tumours and their metastases have been published (Campbell, 1937a), and others not yet represented are shown in the accompanying twelve photographs

taken by Mr. F. V. Welch of this institute (Plate, Figs. 1A to 8B). At one time mouse tumours were all considered to be simple and non-metastatic because evidently they were observed only in younger mice, the mice being killed early. This idea can no longer be held, and there seem to be really no fundamental differences from human lung tumours. Benign adenomas occur in man similar to some seen in mice. Human lung cancer cells are generally classified as squamous, columnar, spheroidal, polygonal, round, and oat: representatives of all these have been seen in mouse cancers, although there may be some minor differences. In mice, although some cases of epidermoid cancer occur (Wells *et al.*, 1941), the squamous cells are seen in their lungs usually only as metastases from skin cancer due to painting the mouse's skin with tar. In man, metastases are seen more often than in the mouse, but this may be due to differences in the vascular beds or to the erect position of the human body. Also, metastases in the brain are common in man but, so far as is known, have not yet been reported there for the mouse, although one has been reported in the skull (Wells *et al.*, 1941). In addition human lung cancers are usually described as bronchiogenic, while only a few of the mouse cancers seem so closely connected with the larger bronchi; but it seems impossible to exclude completely some connexion with terminal bronchioles. Often the mouse lung cancers are described as alveolar cancers, while only 5% of human lung cancers are thus designated (Neubuerger and Geever, 1942). Such differences may be due merely to the different lay-out of the lungs in mice and man. It may be concluded that there are no sound reasons why the results obtained with the mouse experiments may not be applied to human beings. Certainly the dust experiments often seem to produce malignant tumours similar to those seen in man.

Summary

There is a similarity between human lung cancers and mouse lung cancers as regards: (1) agents which increase the incidence of these tumours; (2) the time or age factor; (3) some aspects of the factor of susceptibility; (4) morphology of the tumours.

Although the main effect of certain dusts in development of lung cancer appears to be of a prolonged chemical nature, it is not possible at the moment to exclude entirely some effect of prolonged mechanical irritation by the harder or larger collections of dust. A method for comparison of the degree of dust deposit in the various experiments is given for the first time.

The increase in incidence of lung tumours in mice by certain dusts—tarred road-dust with and without the tar, Czechoslovak pitchblende dust, iron oxide, silica, a "nickel" dust mixture—is statistically significant, although in most cases the average deposits of dust in the lungs are of moderate degree only or less. Care should be taken to reduce exposure to these dusts.

Dusts produce a hypertrophy of lymph tissue in the lungs and in the tracheo-bronchial lymph nodes.

Some further illustrations of mouse lung cancers and their metastases are given.

There is no fundamental reason why the results obtained in mouse experiments with dusts should not be applied to man.

I am indebted to Dr. A. Bradford Hill for some help and advice with the statistical analysis; also to my technical assistant, Mr. C Pergande; and to Mr. F. J. Higginson for cutting and staining the sections.

THE WAR NEUROSES: THEIR NATURE AND SIGNIFICANCE

BY

W. RONALD D. FAIRBAIRN, M.A., M.D., D.Psych.Ed.
Formerly Visiting Psychiatrist, Emergency Medical Service

The following conclusions which I have reached regarding the nature of the so-called "war neuroses" are based upon my experience of psychopathological conditions among military personnel during the present war, and more particularly in a special hospital which until recently formed part of the Emergency Medical Service.

The Traumatic Factor

The term "war neuroses" covers a great variety of clinical conditions; and there is now fairly general agreement among psychiatrists that, so far as symptomatology is concerned, the war neuroses possess no distinctive features differentiating them sharply from the various psychoneurotic and psychotic states which prevail in time of peace. Some psychiatrists have accordingly suggested that it would be more accurate to speak of "the neuroses in wartime" than to speak of "the war neuroses." On the other hand, there are psychiatrists who maintain that where cases among military personnel are concerned a distinction must be drawn between (1) a group of psychopathological states which appear to be precipitated by active warfare and (2) familiar psychopathological states which chance to occur during the course of military service but which might equally well have occurred in civilian life. This attempted distinction appears to be based on the observation that in an appreciable proportion of military cases a psychopathological state is found to have supervened upon some traumatic experience associated with warfare (e.g., a near shell-burst or bomb explosion). In contrast to this observation it is to be noted that "traumatic neuroses" are by no means unknown in time of peace; and here it must be kept in mind that, if such neuroses are less common in peacetime than in wartime, so also are violent traumatic experiences themselves. Actually it is not uncommon to find that a soldier suffering from a traumatic neurosis acquired in war has a previous history of a traumatic neurosis acquired in civilian life. In an appreciable percentage of military cases, too, the trauma upon which a "war neurosis" supervenes is found to be one (e.g., a motor accident) which is only incidentally associated with conditions of war. It is impossible, however, to dismiss the question of the part played by traumatic experiences in the precipitation of war neuroses without pausing to consider what constitutes a traumatic experience.

It is all too often assumed that a traumatic experience is one which produces a psychopathological state *de novo* Yet, when investigation is sufficiently painstaking, it is rare to find a case in which evidence of pre-existing psychopathological characteristics cannot be detected in the previous history. It is reasonable to conclude, accordingly, that a traumatic experience is one which serves to precipitate a psychopathological reaction through the activation of pre-existing but hitherto latent psychopathological factors. The correctness of this conclusion is confirmed by the fact that in certain cases it is possible to detect a very high degree of specificity in the traumatic experience.

Admittedly in many cases the specificity of the traumatic experience is by no means easy to establish. Nevertheless this in itself may not be without significance once the principle of specificity has been recognized. Significance may also be attached to the fact that in many cases it is far from obvious why a situation precipitating a psychopathological state should possess any traumatic quality at all; for many experiences which prove to be traumatic appear comparatively trivial in themselves. Investigation reveals a remarkable range of traumatic experiences, as may be illustrated by the following examples chosen more or less at random from cases that have come under my notice: being blown up by a bomb, being trapped in the cabin of a torpedoed ship, seeing civilian refugees massacred, having to throttle a German sentry in self-defence, being let down by an officer in a tight corner, being accused of homosexuality by another soldier, being refused compassionate leave to go home for a wife's confinement, and even being shouted at by the sergeant-major. When we consider the wide range of such a series the question may well occur to us whether in many cases the traumatic experience which precipitates a war neurosis may not be constituted by military service itself.

The Factor of Infantile Dependence

On the basis of data collected in the course of private psychotherapeutic practice I have gradually found myself driven to the conclusion that all psychopathological developments in the adult are ultimately based upon a persistence into later life of an exaggerated degree of that emotional dependence which is characteristic of childhood, and more particularly of infancy. The all-round dependence which distinguishes childhood requires little emphasis. It is a biological fact bound up with the extreme helplessness of the human infant at birth; and it provides the rationale of that most basic of all social institutions, the family. Since the family constitutes the primal social group, the dependence of the child, psychological no less than physical, is focused essentially upon his parents. In particular it is round his parents that his emotional life revolves; for they are not only his original love-objects but also the original objects of his hate and the objects to whom his earliest fears and anxieties are attached. In the ordinary course of development the individual's dependence upon his parents (and upon parental figures who come to deputize for them) undergoes a progressive decrease throughout the phases of childhood and adolescence until the comparative independence of maturity is reached. It is uncommon, however, for the process of emotional emancipation to prove a smooth passage; for even under the most favourable of conditions there is always a certain conflict between a progressive urge to abandon the state of infantile dependence on account of the many limitations which it imposes and a regressive urge to cling to it on account of the many advantages which it confers. Where conditions are unfavourable this conflict assumes exaggerated proportions, is accompanied by marked anxiety, and gives rise to exaggerated reactions. Whatever adjustments and compromises may issue from an acute conflict of this nature, its most significant consequence is the perpetuation of an attitude of infantile dependence in the emotional sphere—an attitude which is none the less present at deep levels of the psyche even when at more superficial levels it is overcompensated by an attitude of quasi-independence representing nothing more than a denial of the dependence which persists at a deeper level. It is the undue persistence of such an attitude of infantile dependence that I have come to regard as the ultimate factor predisposing to all psychopathological developments; and, in conformity with this view, all psychoneurotic and psychotic symptoms must be interpreted as essentially either effects of or defences against the conflicts attendant upon a persistent state of infantile dependence.

I was already well on the way towards formulating this point of view when it became one of my duties to investigate cases of "psychoneurosis" among military personnel on a considerable scale. I was thus most conveniently presented at the appropriate moment with a unique opportunity of testing the validity of my emergent views by means of a comprehensive survey of a large number of patients who had been suddenly removed from their normal environment, separated from their love-objects, and isolated from all the accustomed supports upon which a dependent person would ordinarily rely. The result was to confirm my conclusions in a most striking manner, as could be abundantly illustrated by clinical material if space permitted.

If the relationship between the development of a war neurosis and the persistence of infantile dependence is not equally obvious in all cases, this is partly because infantile dependence, in common with all characteristics, is subject to an infinite degree of variation; but it is chiefly due to the fact that the anxieties to which the state of dependence exposes the individual call into operation, in varying degrees, a number of mental defences which conceal the true position. Here it must be pointed out that a number of psychopathological symptoms themselves constitute desperate forms of defence against the anxieties attendant upon infantile dependence. At the same time there is another category of symptoms which must be regarded as products of a fundamental attitude of infantile dependence rather than as defences against its effects; and of these the most obvious and significant is unquestionably separation-anxiety. Not only is separation-anxiety invariably present in war neurotics but it is the only single symptom that is universally present. This symptom must accordingly be regarded as the greatest common measure of all forms of war neurosis.

Separation-anxiety

Separation-anxiety is so universal a feature of the war neuroses that it is difficult to believe that its prevalence can have escaped observation hitherto; and, indeed, the literature of the war neuroses does contain various references not only to this phenomenon but also to the occurrence of an exaggerated degree of dependence among neurotic soldiers. To the best of my knowledge, however, the universality and the real significance of these phenomena have never been properly appreciated even by those who have not been oblivious to their existence. The commonest interpretation placed upon them is to the effect that, like many a physically disabled soldier, the neurotic soldier wants to go home because he is ill. Even on this assumption, however, it should be remembered that the effect of illness of any kind is to produce a state of helplessness, which tends to revive an attitude of infantile dependence; but, so far as the neurotic soldier is concerned, the truth would appear to be not so much that he craves to go home because he is ill as that he becomes ill because he craves to go home. It is impossible, therefore, to draw any real distinction between the war neuroses and "home-sickness."

Another common, and misleading, interpretation of the phenomenon of separation-anxiety is that it is really secondary to anxiety over situations of danger, and that it is therefore a by-product of the self-preservation tendency. This point of view would appear to ignore the prevalence of suicidal thoughts and impulses among neurotic soldiers—a fact which is difficult to explain in terms of self-preservation. It would also appear to ignore the frequency with which breakdowns occur under military conditions involving little prospect of personal danger—e.g., among troops stationed in the Shetlands, where isolation rather than danger is the predominant feature of the soldier's life. It may be argued, however, that the wounded no less than the neurotic soldier is often found to exploit, if not actually to welcome, his disability as a means of escape from the dangers of the battlefield, and that the hope of receiving a "blighty" (to use the terminology of 1914-18) is not far from the conscious thoughts of many a good soldier in face of the enemy. It would be idle, of course, to deny the strength of the self-preservation tendency or the influence of personal danger in provoking a state of anxiety; but it still remains to be explained why some soldiers should break down in face of danger while others do not. The explanation would appear to be that the capacity to endure danger varies with the extent to which the individual has outgrown the stage of infantile dependence; and this explanation is in conformity with the notorious proneness to anxiety which characterizes the child as compared with the mature adult.

The Compulsion to Return Home

The significance of the part played by infantile dependence in the aetiology, and by separation-anxiety in the symptomatology, of the war neuroses may perhaps best be judged by the compulsiveness of the desire to return home that is such a marked feature in all cases. In cases in which the general symptomatology assumes a psychoneurotic form this compulsion, although experienced, is seldom so urgent as to give rise to marked disturbances of behaviour. In cases in which the general symptomatology assumes a psychotic form, however, the situation is otherwise; and in such cases it is not uncommon for the compulsion in question to manifest itself either in a fugue or in a consciously executed flight such as to constitute, from a disciplinary point of view, either absence without leave or desertion, or else, where the individual's sense of duty is strong enough, in an attempt at suicide.

Emotional Identification

The presence of a compulsion to return home in association with separation-anxiety is of special significance on account of the light which it sheds upon the psychology of infantile dependence; for it serves to direct our attention to the mental process which constitutes the distinctive psychological feature of this state. The process in question is that of *identification* —a process in virtue of which the individual tends to identify himself emotionally with, and *pari passu* fails to differentiate himself from, those upon whom he depends. So far as we can conceive the mental state of the child before birth, we must regard it as characterized by a degree of identification so absolute as to preclude its entertaining any thought of differentiation from the maternal body which constitutes its whole environment and the whole world of its experience. The process of identification which subsequently characterizes the emotional relationships of childhood would thus appear to represent the persistence into extra-uterine life of an emotional attitude existing before birth. So far as it influences behaviour, it would also appear to represent an attempt to restore emotionally an original state of security which was rudely disturbed by the experience of birth.

The figure with whom the dependent individual originally identifies himself is of course his mother; and, while it is not long before he begins to identify himself with other figures, particularly his father, the original identification persists underneath all others subsequently made. The extent to which this original identification persists, even in individuals who have relatively outgrown the state of infantile dependence, may be judged from the frequency with which the wounded soldier is known to cry out for his mother in his agony. It remains true, nevertheless, that the more emotionally mature an individual becomes the less his emotional relationships are characterized by identification. In the necessarily dependent phase of early childhood it is of course both natural and inevitable that identification should play a predominant part; but when emotional development is satisfactory there is a progressive decrease in identification throughout the years of childhood and adolescence until the relative independence of emotional maturity is reached. This progressive decrease in identification is accompanied by the progressive increase of a capacity on the part of the individual to differentiate himself from emotionally significant figures. At the same time the importance of the figures with whom he originally identified himself (parents and parent-substitutes) tends to diminish. Emotional maturity is consequently characterized not only by a capacity to sustain relationships with other individuals on a basis of mutual independence but also by a capacity to contract fresh relationships. These capacities are deficient in the individual who fails to outgrow the stage of infantile dependence. Such an individual remains childishly dependent upon his home and his loved ones; and he is so closely identified with them that he cannot endure any great measure of separation from them. As was the case in his childhood, they still constitute not only his emotional world but even, in a sense, himself. He feels that he is part of them and, equally, that they are part of him. In their absence his very personality seems to be diminished—and even his sense of personal identity may be compromised. Such being the case, it is not difficult to understand that, when placed under military conditions, he finds it too difficult a task to establish himself as a separate personality within the framework of the military organization, subordinate himself to the aims of the military group without any surrender of individuality, and maintain stable emotional bonds with the group while remaining differentiated from it. On the other hand, he usually finds great difficulty in either establishing or maintaining a reliable relationship with the military group on a basis of identification. This is due, of course, to the fact that his identification with his home and his loved ones proves too strong to admit of a competitor; and it is to the strength of this identification above all that the development of a war neurosis must be attributed.

The Factor of Morale

It should now be evident that identification, which is such a characteristic feature of the emotional life of the dependent individual, is not only the fundamental process underlying the development of a war neurosis but also a process imposing serious limitations upon the social adaptability of the potential war neurotic. That the process of identification should prove to be a common factor operating both in the direction of compromising social relationships and in that of promoting psychopathological developments in the soldier is a consideration in the light of which the whole problem of the war neuroses assumes an aspect that has hitherto suffered from almost complete neglect in medical literature. It is true that during 1914-18 there arose a powerful school of psychotherapists who regarded the war neuroses as products of a conflict between the soldier's instinct of self-preservation and his sense of military duty—the symptoms of the war neurotic being interpreted as motivated, albeit quite unconsciously, by a desire to find a means of escape from the danger zone without experiencing the sense of guilt which a deliberate dereliction of duty would involve. This view, at any rate, had the merit of recognizing the bearing of questions of social responsibility upon the aetiology of the war neuroses. Nevertheless, quite apart from what is now seen to be the superficiality of such an interpretation of the war neurotic's symptoms, no real attempt was made to explain the incidence of the war neuroses; and the conflict in which they were held to originate was treated as essentially a problem of individual psychology. In particular, no account was taken of the general character of the war neurotic's social relationships or of the underlying factors which determine it. Subsequent to the war of 1914-18, attempts were made, particularly under the influence of Freud's conceptions, to obtain a deeper understanding of the war neuroses; but the general tendency was to lay greater rather than less emphasis upon the individual nature of the war neurotic's emotional conflicts. This might have been otherwise if the line of thought pursued by Freud himself in his *Group Psychology and the Analysis of the Ego* had received more of the attention it deserved.

Among the various conclusions recorded by Freud in the work in question is one to the effect that the state of panic notoriously associated with the collapse of an army in the field is essentially due to a breakdown of the emotional bonds which unite members of the military group to one another under common leaders. According to the ordinary view, of course, it is when the situation of "every man for himself" arises that the group spirit (*esprit de corps*) disintegrates. According to Freud, on the contrary, it is when the group spirit becomes weakened that the situation of "every man for himself" arises and that panic invades the individual heart. It is thus not a case of the group spirit collapsing because the individuals who compose the group have given way to panic, but of panic assailing these individuals because, owing to the collapse of the group spirit, they have ceased to be members of a group. The essential feature of the situation is that each quondam member of the group becomes deprived of the support both of his former fellow-soldiers and of the military group as a whole, and is relegated to the status of an isolated individual facing the combined strength of a hostile force without any support. Confronted with such a perilous situation, it is small wonder if the soldier is assailed by panic. It is, of course, *mass* anxiety that Freud is here discussing; but those who have followed my argument will have little difficulty in recognizing that the phenomenon of panic to which he refers is essentially one of separation-anxiety affecting all (or nearly all) the members of a military group simultaneously. The panic-stricken condition of soldiers belonging to an army which has collapsed in the field must accordingly be regarded as one of transient war neurosis occurring under special conditions in individuals who are preponderantly "normal." The difference between the state of such soldiers and that of soldiers suffering from a frank war neurosis is then seen to lie in the fact that, whereas in the case of the "normal" soldier acute anxiety occurs only when the bonds uniting the group as a whole are dissolved, in the case of the neurotic soldier separation-anxiety may occur even when the bonds uniting the group as a whole remain intact. This means, of course, that the bonds uniting the neurotic soldier to the military group are unduly slender and precarious. They are slender and precarious because he has retained from his childhood an excessive degree of infantile dependence and has remained, at any rate at the deeper mental levels, so closely identified with his original love-objects within the family group that he is not capable of establishing any stable emotional relationship with the military group, or of participating adequately in that group spirit which is so indispensable to military efficiency and which is the essence of "morale."

That even the "normal" soldier may develop a war neurosis, albeit a transient one, in circumstances in which morale becomes impaired can leave us in no doubt regarding the intimate connexion of the question of morale and the question of the war neuroses. This phenomenon also serves to show that some measure of infantile dependence may be revealed even in the case of the most "normal" individual—the fact being that emotional maturity is never absolute, but always a matter of degree. In the light of what happens when an army collapses in the field we are further entitled to draw the conclusion that, whilst any high degree of infantile dependence is in itself inimical to morale, the existence of a high state of morale within a group can exercise a profound influence in counteracting the ill effects of infantile dependence among its members. In conformity with this view it has been strongly maintained by well-informed military opinion that during the war of 1914-18 the incidence of war neurosis varied between units in inverse proportion to their morale; and this opinion would appear to be capable of statistical verification even when allowance is made for the idiosyncrasies of regimental medical officers. The incidence of the war neuroses in an army may thus be regarded as a criterion of morale.

The Real Significance of War Neuroses

Reference has already been made to the view, widely held by psychotherapists during the last war, that the war neuroses derived their significance from the fact that their symptoms provided the affected soldier with an unconsciously motivated means of escaping from the dangers of the battlefield with a good conscience. The limitations of this view at once become obvious when we consider that many soldiers contract typical war neuroses without ever having been near a battlefield, and even in the absence of any great prospect of being near one. Actually, as I have tried to show, it is to the symptom of separation-anxiety that we must look for the real significance of the war neuroses. It is towards a return to his home and his loved ones, rather than towards an escape from the dangers of the battlefield, that the neurotic soldier is orientated. At the same time the older view just mentioned does embody an observation which, when properly interpreted, is certainly of great significance. This is the observation that the neurotic soldier characteristically displays a remarkable absence of guilt over his evasion of military duties. Such an absence of guilt is not invariable; for in a proportion of cases with depressive and obsessional features there is a definite tendency on the part of the patient to worry over letting his country or his unit down. Even in such instances, however, one usually gains the impression that the individuals concerned have actually given up all real effort, and that their apparent scruples amount to little more than lip-service to abandoned standards of the past. Further, in so far as such self-reproach is genuine, it is only in the prodromal stage of the war neurosis that it assumes an acute form—i.e., in the stage at which there is real conflict between the desire to return home and the sense of duty. This is usually before the individual reports sick; for by the time such individuals report sick the issue of the conflict is already almost invariably decided. With the exception of these cases, however, neurotic soldiers display a remarkable absence of self-reproach over the failure in military duty involved in their neuroses. This holds true not only of conscripts who have perhaps entered military service with reluctance but also of volunteers who have joined the Army out of patriotic motives.

It is evident, therefore, that the war neuroses are characterized not only by separation-anxiety but also by a definite deterioration of the sense of duty—i.e., by a definite disintegration of the mental structure of conscience. An unmistakable disturbance of the personality is thus seen to be involved in the development of a war neurosis. This disturbance is part and parcel of the regression involved in that revival of a hidden state of infantile dependence to which, as we have seen, a war neurosis is to be ultimately ascribed. What happens is that the war neurotic regresses, in greater or lesser degree, to an infantile level corresponding to a stage of development at which the structure of conscience has not yet been organized upon a stable basis. The neurotic soldier is thus more or less reduced to the emotional state of a child who has not yet reached the stage of accepting his parents as authoritative conscience-figures. At this stage the child is not so much concerned whether his own behaviour is good or bad (morally) in the eyes of his parents as whether his parents appear to love him or not—i.e., whether, from his point of view, they present themselves to him as good (in the sense of "nice") or bad (in the sense of "nasty") figures. What happens, therefore, when a soldier develops a war neurosis is that, regressing to an infantile emotional level, he ceases to regard his superiors in rank and the military organization in general as authoritative parental figures to whom he is bound by a deep sense of moral obligation, and begins to regard them as "bad" parental figures who have no love or consideration for him. At the same time he identifies those at home with "good" parental figures who love him, and who will look after him if only he can get back to them (distance often lending no little enchantment to the view). He thus becomes consumed by an overwhelming desire to escape from the insecurity which he experiences at the hands of the "bad" figures, into whose clutches he feels that military obligations have delivered him, to the security which the "good" figures at home seem, by contrast, to offer him.

That this is a correct interpretation of the situation which develops is confirmed in an interesting manner by two of the stock complaints voiced by neurotic soldiers in proof of their inability to "go back" to the Army. These are (in all cases almost identically phrased): "I can't stand being shouted at," and "I can't eat Army food"—the latter complaint being almost invariably followed in the case of married men by the remark, "But I can eat anything my wife cooks for me." The inner meaning of these complaints is, of course, that every word of command has become the shout of an angry father, and that every "greasy" (always "greasy") meal from the cookhouse has become additional evidence of the indifference of a heartless mother. Further evidence that the neurotic soldier feels himself to be in the power of evil figures is provided by the frequency of such symptoms as a sense of being watched, as well as by the frequency of nightmares about being chased or shouted at (not to mention somewhat less common nightmares about being crushed, strangled, or visited by ghosts). Such being the situation, it is not difficult to understand why it is that the war neuroses should prove so resistant to psychotherapy—and indeed to any form of remedial treatment in the medical armamentarium. Perhaps it is small wonder too that, after acquiring some disillusioning experience of neurotic Service men *en masse*, I was driven to remark, "What these people really need is not a psychotherapist, but an evangelist." In the light of further experience I see no reason to think that this remark was greatly in error; for I remain convinced that, from the national standpoint and from the standpoint of military efficiency, the problem presented by the war neuroses is not one of psychotherapy but one of morale.

I desire to acknowledge my indebtedness to the Department of Health for Scotland for permission to publish this paper, in so far as it is based on my experience as Visiting Psychiatrist in the Emergency Medical Service.

The report for 1941 of the South African Institute for Medical Research records expansion in all branches of its work to meet the needs of war. The training of medical men and technicians for military laboratories continued, seven courses being given: three for technicians in general field laboratory work, two for officers in general pathology, and two for officers in blood transfusion. An investigation was made into the possibilities of extracting vitamin C from natural sources available in the Union. Fresh guavas were found to be by far the richest source, equal, if not superior, to rose-hips in Europe. The skin and outer pulp yielded the most ascorbic acid, and fruit gathered immediately before it was fully ripe showed the maximum vitamin content and the greatest stability of the vitamin during storage. In a series of canning experiments under actual factory conditions some modifications of standard procedure were found to be desirable—namely, the selection of fruit at the correct stage of maturity, the retention of the skin, and the removal of seeds. The dried fruit was also investigated, and it was found that if the fruit was first blanched a powder containing 3 to 4.5% of vitamin C could be produced. From this powder guava sweets were prepared, each containing the required daily dose of ascorbic acid. Provided the preliminary drying had been thorough these sweets, wrapped in dark transparent paper and packed in pliofilm, withstood six weeks' incubation at 110° F. without appreciable loss of ascorbic acid or any deterioration in flavour colour, or palatability.

ABORTUS FEVER

BY

D. G. LEYS, D.M., F.R.C.P.

Physician, Royal Northern Infirmary, Inverness; Consulting Physician to the Northern Counties

Brucella abortus infection in cattle is very common. No doubt a good farmer eradicates known cases from his herd, but I have been told that it is an accepted practice in dairy-farming districts to send infected animals to the sales. The danger of infection to man is from mastitis in the cow, when Brucella is conveyed in the milk or through an abrasion in the hand of a farm worker. The disease is not notifiable, and it is difficult to estimate its incidence; since its symptoms are often trivial, very variable, and never distinctive, diagnosis depends almost entirely on the agglutination test, and there seems little doubt that the true incidence is several times that of the recognized cases. Subclinical infection is probably very common. Huddleson (1939) refers to a study in school children which disclosed a significant agglutination titre in 40% after all had drunk infected milk, when only two of the children developed symptoms of the disease; agglutination titres in symptomless subjects rose as high as 1 : 12,000, and many had titres of 1 : 320. These children were observed over a period of more than a year, and the development of maximum agglutination was often a matter of months. Wilson (1942) estimates that 500 cases per annum occur in England and Wales.

Human cases of the disease were not recognized for many years after it was known that infection in cattle was common; mortality is low, and the disease does not appear to be a cause of abortion in women, for more than one case has been observed in an undisturbed pregnancy. The number of Brucella in infected cows' milk is far less than of *Br. melitensis* in goats' milk, and this may account for the relative mildness of abortus fever as compared with undulant fever. The two organisms can only be distinguished serologically, and the clinical course of the infection is very similar.

The general picture of the disease is that of an insidious onset (with uncertain but probably long incubation), a prolonged course of anything up to several months but usually some weeks, with limb pains and sweating as the prominent symptoms, an undulant type of fever, leucopenia, and negligible (possibly no essential) mortality. This is a true account of many cases, making a picture easily kept in mind, and if the blood of every patient presenting it were examined for *Br. abortus* agglutinins the great majority of cases would probably be diagnosed. One might perhaps question the need for laying stress on the importance of correctly diagnosing a disease which is essentially not fatal, which causes no lasting disability, and which is very possibly not amenable to any specific treatment. The importance is twofold: (1) the infection is a cause of a good deal of prolonged invalidism, and if there is no recognition of its prevalence there will be the less energetic search for a cure and for measures to eradicate it; (2) a true diagnosis will often serve greatly to relieve the mind of patient and doctor, and may prevent a long-continued enforced period of medical observation and inactivity for suspected tuberculosis. Abortus fever is a more likely diagnosis than tuberculosis in patients who have sweating as the presenting symptom.

Quite a high proportion of abortus fever cases, however, have bizarre symptoms, and these may present in such a way as to make diagnosis most difficult. Huddleson thinks that "latent" infection may become evident after some intercurrent, perhaps trivial, illness; on the other hand, in one of my cases the onset of the fever was the signal for the development of a streptococcal endocarditis. It seems worth while to give an account of 8 cases which I saw between June, 1938, and June, 1942, because of the extraordinary diversity of their symptoms: so much is this diversity impressed upon one by even such a limited experience of the disease that the diagnosis is automatically considered in every case of fever unexplained after a few days. In the central laboratory of the area an agglutination for *Br. abortus* is included in every Widal reaction.

The endemic nature of the infection is shown by the time of onset of these 8 cases from one area:

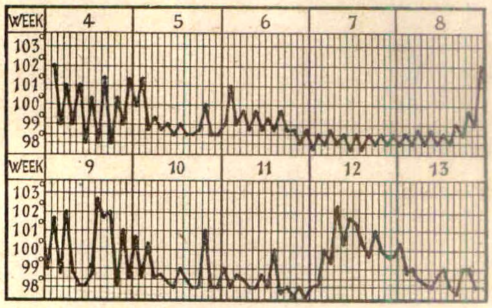
1938			1939				1940				1941				1942		
	1				1	1	1			1		1	1			1	

Only one case had direct contact with cows: the others were therefore all due to infected milk. The provisional diagnoses before the finding of positive agglutination were: typhoid (1), pyelitis (1), pulmonary tuberculosis (1), meningitis (2), bronchitis (1), neurosis (1), rheumatism (1)—i.e., in no case was a correct diagnosis made immediately, and most of the patients had been ill for some weeks before the diagnosis was proved.

Case I: Typical Undulant Fever with Psychosis

A married woman, aged 49, with a lifelong history of psychosomatic symptoms. First seen Jan. 3, 1942. Diagnosis of abortus fever on Nov. 16, 1941, when agglutination titre was 1 : 1,600. History then about 3 weeks, and symptoms: constipation, rigors, sweating, limb pains, and exhaustion. Two attempts to give sustained treatment with a sulphonamide abandoned for lack of co-operation. Three undulations of fever (see Chart).

Condition of Patient in the Eighth or Ninth Week of Illness.—Apathetic, querulous, and discontented. Complete insight into her condition. No lack of emotional control at this stage. Required trained nursing at home and made life difficult for the nurse. Attempted to supervise affairs of house and family. Physical condition good, but tongue dry; fairly heavy sweating, almost entirely at night. No pain on movement of limbs. No albuminuria and no physical signs found in nervous system; no enlargement of liver or spleen. Differential cell count on Dec. 30, 1941: P. 66, L. 29, M. 3, B. 1, E. 0.5%. Blood count on Jan. 6, 1942: R.B.C. 4,170,000, Hb 77%, C.I. 0.92, W.B.C. 6,150 (P. 58, L. 40, M. 2). She found it difficult to sleep, and had been given both bromide and barbiturate; a slight tendency to disorientation and to aphasia and to agraphia, which was evident as hesitation in the finding of words, was attributed at this time to the effects of the barbiturate.



Temperature chart of Case I (4th to 13th weeks), showing three undulations of fever

She resisted admission to hospital until Jan. 25, by which time both her physical and her mental condition had deteriorated. She had lost weight and refused food. Her attitude to doctors and nurses was critical and resentful, but there was still complete insight and she was quite prepared to accept the fact that her depression and irritability were the result of her illness. The periods of depression did not correspond with periods of temperature. After admission she had an irregular pyrexia, one definite relapse of the undulant type from Jan. 20 to 27, and thereafter no significant rise of temperature. A little later she developed lack of emotional control and strong paranoid tendencies.

On admission to the Royal Northern Infirmary (Jan. 25) agglutination to *Br. abortus* was 1 : 16,000. An estimate of blood bromide was made on the suspicion that her depression might be due to bromide poisoning, and was 250 mg./100 c.cm. Complete withdrawal of bromide, however, made no impression on the emotional state. There was intermittent albuminuria and the urine sometimes showed pus cells. Her blood culture on Jan. 22 was sterile. The blood count showed a deterioration, and on March 3 was: R.B.C. 2,880,000, Hb 59%, C.I. 1.0.

Comment.—The symptoms in this patient were essentially psychotic, and consisted of depression, apathy, lack of emotional control, slight tendency to aphasia and agraphia, irritability, and suspicion. Throughout there was complete insight into her state

This case can hardly be regarded as a chronic one, because 5 months after the onset she was restored to her usual health. It is notable that the agglutination increased from 1 : 1,600 to 1 : 16,000 between the third and eighth weeks of the illness. There was no notable leucopenia. Sulphonamides were not used effectively because of lack of co-operation, but short trials of 6 g. daily of (*a*) sulphanilamide, (*b*) sulphapyridine, and (*c*) sulphathiazole had no influence on the temperature.

Case II: Bronchitis with Steatorrhoea: ? Pancreatitis: Intermittent Albuminuria

A rigger in the R.A.F. aged 37. History of recurrent bronchitis for 10 years. Was admitted to a military hospital on Feb. 13, 1940, with cough and sweating, present for some weeks. The onset of this attack was described as influenza. Transferred to Royal Northern Infirmary Feb. 22. Febrile; signs of bronchitis. Treatment with sulphapyridine begun, but discontinued because of persistent nausea and subsidence of temperature. Inconstant albuminuria; centrifuged urine contained red cells. Blood urea, 39 mg./100 c.cm. Standard urea clearance, 118% of normal. Blood culture sterile. From the first he complained of tenderness in the epigastrium and abdominal pain, and showed muscle spasm. Profuse sweats. Hb 75%, W.B.C. 13,000 (P. 69, L. 29, M. 2). Agglutination for *Br. abortus* positive 1 : 8,000. Stools rather frequent, very pale. Total faecal fat, March 4, 44 g. % (60% split, 40% unsplit). Urinary diastase 50 units per c.cm., and total urinary diastase 62,500 units in 24 hours. March 18: total faecal fat 50.3 g. % (63.1% split, 36.9% unsplit). Serum bilirubin 0.4 mg./100 c.cm. By March 11 his symptoms had disappeared except for slight stiffness in the joints and for the signs of bronchitis.

Case III: Meningism, Pyuria, and Urticaria

A schoolgirl aged 11. Onset Nov. 1, 1940, with vertigo and stiff neck. Seen 3 days later by family doctor, who found nuchal rigidity. T. 101.8° F., P. 130. Spinal fluid normal. Given 6 g. of sulphanilamide daily for ? 3 days. Seen then by medical specialist, who found slight cyanosis, dilated pupils, diminished tendon-jerks, resistance to palpation of abdomen, furred tongue, and an urticarial rash. Urine showed pus cells, and diagnosis of pyelitis was made. Symptoms, however, continued. On Nov. 25 Widal reaction, because of continued temperature: agglutination to *Br. abortus* 1 : 480, negative to typhoid group. Blood culture sterile. Blood counts: Nov. 6—R.B.C. 5,100,000, Hb 83, C.I. 0.82, W.B.C. 3,500 (P. 43.5, L. 36.5, M. 19.5, B. 0.5); and on Nov. 7—W.B.C. 6,500 (P. 69, L. 20, M. 9.5, B. 0.5).

I saw her on Nov. 25: temperature still raised; sweating not excessive; pain in the back and hands and feet. No physical signs. Sulphanilamide 6 g. a day was given again, and was discontinued after 2 or 3 days: complete subsidence of symptoms, which did not recur.

Case IV: Bacterial Endocarditis

A hotel maid aged 19. Rheumatism at 13; established mitral disease. Seen in hotel July 31, 1939, 12 days after onset of an acute illness with delirium. No headache; no pains in limbs; no dysuria; no diarrhoea; no vomiting. Examination: Flushed; furred tongue; erythematous rash very suggestive of typhoid (about 20 small erythematous spots on trunk and limbs). Agglutination to the typhoid group negative, but positive to *Br. abortus* 1 : 3,000. She was admitted to the fever hospital; on admission, R.B.C. 3,970,000, Hb 68, C.I. 0.85, W.B.C. 7,350. No albuminuria. She was given sulphapyridine 6 g. daily, with short intermissions, for a period of 5 weeks. Temperature showed rises at irregular intervals of a few days and usually persisted for 24 hours; occasionally febrile periods would last 3 days. Temperature never reached a higher level than 101° F. The temperature chart suggested a recrudescence of temperature whenever sulphapyridine was stopped. Erythematous rash reappeared on Oct. 5.

Transferred to Royal Northern Infirmary on Nov. 6, 1939: R.B.C. 2,360,000, Hb 34, C.I. 0.72, W.B.C. 14,150 (P. 77, L. 18, E. 1, M. 3.5). Platelets 123,610 per c.mm. Reticulocytes 2.5%. Blood film showed anisocytosis, poikilocytosis, and polychromasia. Examination: Very pale; furred tongue; tachycardia; B.P. 140/70; albuminuria—centrifuged deposit of urine showed red cells. Blood urea 135 mg./100 c.cm. No embolic phenomena apart from the kidneys. Agglutination to *Br. abortus* 1 : 120. Blood culture: *Str. viridans*. Further attempts were made to treat this patient with sulphapyridine and heparin, but she shortly afterwards died of uraemia. No necropsy was allowed.

Case V: Typical Mild Case with Sweating and Limb Pains

A labourer aged 20. Seen at Royal Northern Infirmary as out-patient on April 15, 1941. He had been off work for 4 weeks with "influenza." The symptoms were of limb pains, headache, and sweating. The sweats occurred about midnight, and he was referred to hospital because of the sweating. During the daytime he had no symptoms. Had not lost weight. Examination: A thin, nervous man with acne. No physical signs found. Sweats thought to be emotional, but blood sedimentation rate 7 mm. (Westergren), and agglutination to *Br. abortus* positive 1 : 8,000.

Case VI: Mild Case; Onset with Rigors

A bank clerk aged 25. Diagnosis here less certain than for the others. Admitted to Royal Northern Infirmary 2 weeks after onset of illness with slight rigor. An old case of pulmonary tuberculosis with maintained pneumothorax: last refill the day after onset of symptoms. Temperature raised from beginning of symptoms, and a week later pain in limbs and joints and headache, but no joint effusions. R.B.C. 4,350,000, Hb 73, C.I. 0.81, W.B.C. 7,950 (P. 76, L. 21, M. 3). Agglutination to *Br. abortus* negative on July 14, 1941; agglutination positive 1 : 120 on July 21, and positive 1 : 60 on July 27. B.S.R. on July 19, 21 mm. (Westergren). Blood culture sterile; stool culture negative. Treated with sulphathiazole, 1 g. 6-hourly; immediate subsidence of temperature and symptoms.

Case VII: Pleural Pain, Dyspnoea, and Tonsillitis

A soldier aged 44. Sent to hospital Oct. 3, 1939, as suspected case of pulmonary tuberculosis. Easily tired, breathless on exertion; nocturnal cough, pleural pain, sweating; sore throat one week before admission; no gastro-intestinal symptoms; no limb pains. Examination: Not severely ill; signs of bronchitis; no rash; sputum, no T.B.; B.S.R. 3 mm.; W.R. negative; W.B.C. 14,250 (P. 61.5, L. 30.5, M. 7). Agglutination to *Br. abortus* positive 1 : 4,000. Treatment with sulphanilamide without any spectacular result, and symptoms still present on Nov. 19, 1939.

Case VIII: Meningism and Ocular Palsy

A farm servant aged 15. Admitted to hospital July 30, 1938, three weeks after onset of illness, with rigor, sweating, and exhaustion. Seen by doctor, but no diagnosis made. Improved. Returned to work for one week, when symptoms recurred with severe sweating and frontal headache. Intermittent diplopia from onset. Examination July 30: Flushed, sweating, dilated active pupils, normal fundi, slight nuchal spasm, and positive Kernig's sign. Left sixth nerve palsy. Spinal fluid twice examined; completely normal. Remained febrile for 3 weeks; symptoms and signs then gradually subsided. Sixth nerve weakness observed intermittently. No albuminuria. Agglutination to *Br abortus* positive 1 : 16,000 on Aug. 6, and positive 1 : 960 on Aug. 17. W.B.C. 6,350 (P. 55, L. 21, M. 20, E. 4). W.R. negative. Blood culture sterile on Aug. 12.

Comments

1. In none of these cases was enlargement of liver and spleen noted.

2. Anaemia was not a feature apart from intercurrent or pre-existing disease, nor did any case show an important loss of weight.

3. *Leucocytes.*—A considerable diminution in the polymorph count and in the monocyte count, without any proportionate increase in the lymphocytes, is considered characteristic of *Br. abortus.* Only one of these patients, however, showed any material reduction in the polymorphs (Case III; total polymorphs 1,505), but the next day this child's polymorph count had increased to 4,485. The monocyte count was certainly rather low in several cases, the lowest figure found being 122. One case (No. VIII) had a total monocyte count of 1,260, which is a high figure—so high, in fact, that mononucleosis was considered as a possible diagnosis, as also in Case III, in which the monocyte count was at one time 19.5%. The leucocyte counts are set out in the following table:

Leucocyte Counts

Case	Age	Total	P. (%)	L. (%)	M. (%)	E. (%)	B. (%)
I	49	6,150	58	40	2	—	—
II	37	13,000	69	29	2	—	—
III	11	3,500	43·5	36·5	19·5	—	0·5
		6,500	69	20	9·5	—	0·5
IV	19	7,350	—	—	—	—	—
V	20	—	—	—	—	—	—
VI	25	7,950	76	21	3	—	—
		10,700	65	32	3	—	—
VII	44	14,250	61·5	30·5	7	—	—
VIII	15	6,350	55	21	20	4	—

4. Blood cultures in 6 cases at various times, and several during the acute phase, were all sterile.

5. Blood sedimentation rate was estimated only 3 times. It was 7 mm. in Case V, 21 mm. in Case VI, 3 mm. in Case VII (Westergren 1 hour). One might perhaps suggest that high

rates are not found because of the absence of any massive inflammatory exudate.

6. *Skin Eruptions.*—Only 2 cases showed rashes which were considered to be due to the disease. Case III had an urticarial type of eruption, and Case IV in the early stages an eruption indistinguishable from typhoid, which was the original clinical diagnosis. According to Huddleson a typhoid-like eruption is frequent.

7. *Agglutination.*—Agglutination titres with the corresponding period of the disease are given below:

Agglutination Titres

Case I: At 3 weeks, 1 : 1,600; at 12 weeks, 1 : 16,000
" II: At 7 weeks, 1 : 8,000
" III: At 4 weeks, 1 : 480
" IV: At 2 weeks, 1 : 3,000; at 5 months, 1 : 120
" V: At 4 weeks, 1 : 8,000
" VI: At 1 week, nil; at 2 weeks, 1 : 120; at 3 weeks, 1 . 60
" VII: At 4 weeks, 1 : 4,000
" VIII: At 4 weeks, 1 : 16,000; at 6 weeks, 1 : 960

It seems to be agreed that agglutination does not become positive until the second week, probably not until the tenth day from the onset of symptoms, and Huddleson says it may be negative right throughout a chronic case. The minimum diagnostic titre is a little difficult to determine. It will be noted from the above figures that there was no case with a titre less than 1:480, except Case VI, in which diagnosis, apart from the symptomatology, rested upon an increase in the agglutination titre from 0 to 120 during the first two weeks of illness; at the end of the third week it was found to be 1:60. It so happens that this was the only case in which a rather strong impression of the influence of sulphonamide treatment was gained. Harries and Mitman (1940) give 1:100 as the critical level, but consider that in London, where use of pasteurized milk is general and subclinical infections are less common, a titre of 1:80 is suspicious. This figure is also given by Wilson (1942) as significant. Huddleson gives 1:50 as the level for a presumptive diagnosis. Huddleson uses in diagnosis a skin-sensitivity test made from the products of a broth culture in a form which he calls "brucellergen," but the agglutination test seems to provide all that is required for a positive diagnosis.

8. *Unusual Symptoms.*—Meningism is reported by Huddleson as common in Malta. I have found no previous reference to it in abortus fever, nor any reference to ocular palsy. Cases of bacterial endocarditis are reported by Spink and Nelson (1939), who discuss the difficulties of diagnosis, and by Scott and Saphir (1928).

9. *Treatment.*—There is scanty evidence of any positive effects from the use of any special line of treatment. Huddleson claims a shortening of the infective period by the use of a vaccine. An antimony compound, stibophen (traded as "fouadin"), which is used in schistosomiasis, has been claimed as effective, but the positive evidence is slight (Neumann, 1936). An attempt was made to use this drug in one protracted case, but the appearance of albuminuria after the first dose prevented any further administration. There have been no dramatic or even very encouraging results reported with any of the sulphonamide compounds. All except one of the 8 patients here reported were given a sulphonamide, but without any obvious effect. Sulphapyridine was used in 2 patients, sulphanilamide in 4, and sulphathiazole in 1. In Case VI there was an abrupt termination of symptoms after the use of sulphathiazole; such a mild case, however, is clearly not enough to warrant any definite conclusion.

Summary

A description is given of 8 cases of abortus fever, which is endemic in this country. The disease is benign, but gives rise to great difficulties in clinical diagnosis, and it may be the starting-point of more serious disease. Since milk is almost entirely the source of infection, universal pasteurization would eradicate it. The agglutination test is conclusive in diagnosis.

FOOT-AND-MOUTH DISEASE IN MAN

BY

HENRYK DLUGOSZ, M.D.

With each new epizootic of foot-and-mouth disease (f.a.m.d.) we must consider whether infection of man is possible, and, if so, is it of practical importance? That infection may occur is instanced by the experimental infection of French scientists through drinking infected milk; by similar results among workers in the German research centre on the island of Rügen; and, finally, by positive results obtained in guinea-pig inoculation from certain cases of f.a.m.d. (aphthous fever) in man which have been described in medical journals.

Infection of man is therefore possible, and, although occurrence is rare and characterized by persistent mildness, we consider it to be of no little scientific interest. The rarity of the disease in man (we know of only ten cases prior to the last war, as opposed to many thousands of cases in animals), and its mildness, do not deprive it of interest, as the slightly affected man may start a serious outbreak among valuable live stock. As the disease causes cattle to lose weight and their milk production is lowered the condition is of paramount importance to farmers and exporters. To-day especially, when the need for maximum food production is a major consideration, the early diagnosis of all cases is essential, if only from the purely economic point of view.

I have had the opportunity of observing two cases of f.a.m.d. in man. The first I studied in detail in Poland, in the University Clinic of Lwow. This has been described in *Polska Gazeta Lekarska* (1938, **17**, 501). The second case, that of a Polish soldier, was brought to my notice in Scotland in September, 1940.

Case I

A man aged 40 was wounded in the finger by a splinter from a butcher's table. The wound, although slight, healed very slowly. A transitory lymphangitis and lymphadenitis followed in a few days in the affected arm. Two weeks later general weakness, headache, and febrile manifestations developed, the temperature rising in a few hours to 102° F. These symptoms persisted for three days, the patient believing himself to be suffering from "influenza." On the third day painful mastication and salivation ensued; multiple vesicles appeared in the mouth, later giving way to ulcer formation. The following day the ulcerations were found to be larger, and were bleeding. The doctor, reconsidering his original diagnosis of "aphthous stomatitis," suspected an acute leukaemia or agranulocytosis. Blood examination, however, revealed no abnormality. Within the next few days the temperature had risen to 105° F., the mouth symptoms had increased, and the skin around the mouth showed areas of pustulation. The patient at this stage was sent to the University Clinic.

On my examination (at the end of the first week of the illness) I found the temperature to be 103° F., while excessive salivation was a prominent feature. On the skin around the mouth there were vesicles filled with a serous turbid fluid. Some of these were covered with crusts. Multiple vesicles and small polycyclic ulcers with grey bases were found over the inner sides of lips, cheeks, and palate, the surfaces of the tongue, and on the pharynx. There was slight bleeding from the ulcerating surfaces, and the breath was very foul.

The characteristic sweetish-mouldy smell of the patient reminded me of the smell I once sensed near a cow with foot-and-mouth disease. This smell facilitated the diagnosis. On the skin of the trunk there was a group of vesicles resembling herpes zoster Large erythemata of cherry-red colour were present on the palms, while on the soles there were single polycyclic spots of similar coloration.

On the tenth day the mouth lesions began to heal, but on the palms and around the finger-nails large vesicles appeared. Vesicles appeared also on the soles, but these remained single. During the next few days the mouth lesions had healed, but the vesicles on hands and feet persisted. By the third week of the illness the ulcers of the mouth had healed without cicatrization, and the perioral lesions had disappeared. Finally the vesicles on the hands and feet healed after separation of the epidermis, leaving no cicatrices. There were no sequelae or complications, the temperature gradually returning to normal after the appearance of the vesicles.

Blood examination during the illness revealed no abnormality, but a lymphocytosis was present during convalescence. The red cell sedimentation rate (Westergren–Biernacki) was never above 8 mm. an hour. The Wassermann reaction of the serum was negative. Guinea-pigs inoculated with the serous fluid from the soles and palms developed the typical signs and symptoms of f.a.m.d. after 12 to 14 days.

The Veterinary Office at my request undertook a search for cases of f.a.m.d. in the patient's district, and were successful in locating several cases among cattle. The diagnosis of the disease in man was therefore instrumental in bringing to light unsuspected cases in animals in the same locality.

Case II

A Polish soldier, aged 31 and of previous good health, reported sick on account of vesicles on his hands which made work impossible. He gave a history of general weakness of 14 days' duration. Twelve days previously he had been troubled by vesicles in the mouth and on the inner surface of his lips, which he attributed to burns from hot food. Vesicles had been present on his hands for seven days before reporting. Large quantities of unboiled milk formed part of his normal diet. Examination revealed ulcerated areas on the tongue and inner surface of cheeks and lips. Vesicles with crusts were present round his mouth; while the palms, fingers, and soles showed areas of vesiculation. His temperature was 98.6° F. A diagnosis of f.a.m.d. was made on these findings, and the patient was sent to hospital in Glasgow owing to the proximity of pasturage to the camp.

Commentary

These two cases may serve to show the occurrence of f.a.m.d. in man. Infection may be external, as evidenced by the first case and by the work of experimenters, or via the digestive system as in Case II and in the French researches. The incubation period is apparently about 14 days.

Characteristic findings are the headache and general weakness, and pain in the extremities. About the third day excessive salivation and superficial ulceration of the oral mucous membrane and vesiculation of the skin around the mouth ensue. Later the vesicles appear on the palms and soles and around the nails, being preceded by cherry-coloured erythema. The vesicles contain a turbid serous fluid. All the skin and mucous membrane lesions heal without cicatrization. The temperature is high at first and falls after the appearance of the vesicles, returning to normal by the second week. In a few cases the temperature remains normal throughout. No changes are apparent in any of the internal organs, in the blood, or in the sedimentation rate (an important point in the differential diagnosis of acute leukaemia and agranulocytosis). The disease appears to run a more moderate course in man than in animals.

Differential diagnosis must include aphthous stomatitis, acute leukaemia, agranulocytosis, scurvy, and drug rashes. The distribution of the lesions, blood examination, and guinea-pig inoculation will aid diagnosis. Treatment is purely symptomatic.

Taking into account the appearance of two such cases in my own experience in so short a time, I am in some doubt as to whether f.a.m.d. is as rare in man as I had hitherto believed. Owing to the comparative mildness of the constitutional upset many cases may never come to the notice of the medical man, and not a few cases may be wrongly diagnosed.

Conclusions

The sanitary authorities would be well repaid if more attention were given to the prevention of the spread of f.a.m.d. by man.

There should be co-operation between the doctor and the veterinary worker to prevent human sufferers with f.a.m.d. from having contact with animals.

A new sterilization decree has been issued in Norway by Quisling aimed at "inhibiting the reproductive capacity of mentally or physically defective persons whose children might suffer from the same weaknesses; and of insane or mentally defective people who have abnormally developed sexual impulses and might commit sexual offences." Doctors, prison and hospital officials, police, and social welfare institutions may propose an investigation with a view to sterilization, and decisions will be taken by the Director of Public Health alone. Under the law passed in 1934, the Director of Public Health could decide on cases only after they had been considered by a special board appointed by the public health department.

PREGNANCY AND LABOUR IN A CASE OF CONGENITAL COARCTATION OF THE AORTA

BY

C. W. WALKER, *M.C.*, M.D.

Herefordshire General Hospital

Congenital coarctation of the aorta, being a somewhat rare abnormality and moreover affecting males more often than females, in the proportion of 3 to 1, is seldom seen as an obstetrical complication. Jensen (1938), reviewing the literature, found references to child-bearing in 7 cases of coarctation, the most important account being that of Strayhorn (1936), whose patient showed signs of commencing cardiac decompensation during pregnancy, but was rested and successfully delivered by Caesarean section. Of these 7 patients, two died during pregnancy—one from cerebral haemorrhage, the other from rupture of the aorta into the pericardium; a third died from congestive heart failure 14 days after pregnancy had been terminated. In addition to the foregoing, Bramwell and Longson (1938) give details of a case in which there was dyspnoea and palpitation on exertion from the fourth month onwards; this patient was successfully delivered by Caesarean section, and made an excellent recovery.

Case History

Mrs. A., a farmer's wife, had suffered from tiredness and sudden fainting fits from the age of 8, could not indulge in games, and had to leave school early. She was diagnosed at the age of 20 as a case of congenital coarctation. At this time she was incapable of exertion, and had had her activity greatly restricted for several years; but she became stronger, married, and in the autumn of 1941 became pregnant for the first time, being then 31 years old.

On Nov. 5, when I first saw the patient, she was in the second month of pregnancy and looked well. On examination scoliosis was seen to be pronounced: the heart showed displacement and enlargement to the left, the apex beat being at a level with the lower border of the manubrium sterni and axillary in position, being 6 in. from the midline. A harsh systolic murmur was heard in the second and third intercostal spaces to the left of the sternum, and extending towards the apex: the second sound in this area was sharp and reduplicated. At the apex the first sound was loud and accompanied by a systolic murmur, and the second sound was sharp. The pulse rate was 72, and the blood pressure in the arm 210/100. The blood pressure in the leg was difficult to obtain, but appeared to be about 125 (systolic). Arterial pulsation was marked above the clavicles, but not elsewhere. A radiograph of the heart was similar to one taken 10 years earlier, except that the left border of the heart appeared straighter and the apex almost at the left border of the chest (1/2 in. further to the left than 10 years before): typical rib-notching was present. Apart from left axis deviation there were no abnormal appearances in an electrocardiogram. The pregnant uterus presented no unusual features, the pelvis was of good size, and the urine was normal.

The patient remained extremely well throughout pregnancy, doing her own housework, taking walking exercise, and retiring to bed at 7.30 p.m. Her doctor found no cardiac, arterial, or urinary changes throughout, but on examining her 5 weeks before term he found premature labour to be starting, and she was admitted to hospital.

On admission the patient was seen by a surgical colleague (Mr. B. G. Scholefield), who had seen her in early pregnancy also: he agreed to the continuance of labour, but was ready to perform Caesarean section should this appear advisable. The progress of labour was very gradual, mild pains with 10 to 15 minutes' intervals continuing throughout the day. The patient was given a night's sleep (morphine gr. 1/4, atropine gr. 1/100), and labour continued the next day, dilatation of the os proceeding gradually without producing distress. The blood-pressure reading was unaltered by these pains, though some frontal headache was complained of after 11 p.m., the os being by then almost fully dilated. The change to second-stage pains was dramatic and alarming. These set in with rupture of the membranes, and the patient immediately became acutely distressed and breathless, and complained of severe headache. Pulsation of expansile appearance became pronounced at the root of the neck; the pulse rate was 128. Unfortunately it was impossible to delay to obtain a blood-pressure reading. The patient was at once anaesthetized, and at midnight was delivered by forceps of a living premature child of 5 lb. Convalescence was uneventful, and a radiograph of the heart and an electrocardiogram taken before discharge from hospital three weeks later showed no alterations from those taken in early pregnancy.

Comment

The decision to allow labour to continue rather than have early recourse to Caesarean section was prompted by the following considerations: the patient felt strong and well, was calm and confident, and was anxious to make the attempt; the infant was small and its presentation normal (L.O.A.), so that its passage might reasonably be expected to be an easy one; the early progress of cervical dilatation was free from fatigue and cardiac distress. In spite of these favourable circumstances the labour had to be stopped as soon as second-stage pains set in, as it was obvious that the tension in the upper circulation was being dangerously raised. With a full-time child, a less favourable presentation, a maternal heart having less reserve, or in the presence of more distressing first-stage pains, the danger-point might well be reached before dilatation was complete and delivery possible. This being so, it would appear that in cases of coarctation of the aorta, however favourable, the obstetrical procedure of choice is Caesarean section at the onset of labour.

My thanks are due to Dr. P. King Lewis for permission to publish this case, and for his share in its management.

Medical Memoranda

A Case of Anaphylaxis after Anaesthesia

There has been a general tendency in the last 10 years to perform an increasing number of operations under local anaesthesia, and this tendency has been given an added impetus by the war. Local anaesthetics are cheap, convenient, portable, perhaps require no special training, and are more economical of man-power. It is therefore essential to know something of their relative toxicity.

Toxicity may be due to (*a*) rapid absorption, (*b*) idiosyncrasy, and (*c*) accidental injection into a vein. This last can usually be prevented by suction through the syringe, when the presence of blood is shown in the solution. This means that the needle must be removed and reinserted elsewhere.

In 217 cases of "conduction anaesthesia" with novutox[*] I have met with only one untoward incident. Novutox is the proprietary name for the preparation of 2% w/v solution of ethocaine hydrochloride with adrenaline 0.00002 g. per c.cm. in Ringer's solution with caprylhydrocupreinotoxin HCl in a proportion of 0.00002 g. per c.cm. and thymol 0.0004 g. per c cm.

CASE HISTORY

The patient, a quite healthy individual, complained of severe muscular pain and was given an intramuscular injection of 0.75 c.cm. of novutox in the right flank, the area of maximum tenderness. Ten minutes later he had a severe itch in both arms, pain and dryness of the gums, thirst, and lacrimation. There was shivering, and the eyes became red; the nostrils were blocked, the voice became hoarse, and he was troubled with a severe throbbing pain in the head and frontal sinuses. The face, neck, and hands were livid and unbearably hot. His systolic B.P. was 210, the pulse 115 per minute, and the temperature 105°. He became speechless and dyspnoeic.

The patient's clothes were loosened, and the windows in the room widely opened. He was thoroughly mopped with a wet Turkish towel, which after each application to his face became hot and steaming. After 20 minutes he received 6 drachms of brandy without any effect. Tincture of spirit of ammonia was then given to inhale: this partially cleared the nasal and bronchial passages. In about 45 minutes from the outset he began to speak incoherently in a muffled nasal way. Respiration, though easier, was still laboured, and he now felt cold and shivering. He was at once given a hypodermic injection of two minims of adrenaline hydrochloride, and in exactly 10 minutes was able to dress himself, and his B.P. came down to 180 mm. Hg, the pulse to 84, and the temperature to 99.5°. In another 10 minutes he took a cup of tea and felt much better.

He travelled in a public conveyance home, where I visited him the next day. He was pale but in good humour, joked about his experience, and said that he thought he was going to pass out.

R. ARMATTOE, L.R.C.P.&S.Ed.

---

[*] Novutox does not contain cocaine, is not on the D.D.A., and is five times less toxic than cocaine.

Reviews

NEPHRITIS

Nephritis By Leopold Lichtwitz, M.D. (Pp 328 25s.) London: William Heinemann. 1942.

Prof. Lichtwitz, who is now in New York and who is well known for his many contributions in the past to the German literature of kidney disease, has recently given English workers the benefit of his experience in a short readable volume. A large part of the book is devoted to discussions on the physiology and functional pathology of renal disease, including such conditions as water metabolism, albuminuria, oedema, and uraemia. He describes the method of testing the function and capacity of the kidney which has been in use in his clinics for many years. This, in its simplest form, merely consists of an estimation of the excretion of solid substances by measurement of specific gravity and urinary volume under standard conditions. It can thus be carried out by any clinician without expert laboratory assistance. Further information can be gained by studying the excretion of chloride and urea over a period while the patient is on a special diet designed to test his excretory capacity. This section, the more physiological, is undoubtedly the best in the book, which, however, regarded as a textbook on nephritis, is rather disappointing. The author follows, on the whole, the German school, and his references are very largely of German origin. The more recent work of English and American authors is given scanty consideration or, in some cases, none at all. This is especially regrettable as the work of Goldblatt on hypertension and the recent writings of Ellis and Wilson in this country have done so much to clarify a difficult chapter in medicine.

Lichtwitz does not attempt any satisfactory classification of kidney disease. He deals only briefly with essential hypertension, but does not stress the importance of the malignant type. Even if he holds that this is not primarily a disease of the kidney, it is surely of the greatest importance in differential diagnosis. His consideration of uraemia, again, rather takes us back to the days when there was no clear distinction between true chemical uraemia and many similar symptoms which are caused by acute or chronic states of hypertension. The book is well worth reading by anyone particularly interested in renal disease, as it gives a new viewpoint on many aspects of the subject, and brings the English reader an easy summary of Continental literature. It cannot, however, be considered a comprehensive or even an up-to-date statement of present-day views on nephritis.

HUMAN NUTRITION

Food and Planning. By J. R. Marrack, M.D., D.S.O., *M.C.* With a preface by Sir John Boyd Orr, D.S.O., *M.C.* (Pp. 285. 15s.) London: Victor Gollancz, Ltd. 1942.

This admirable book is about to appear, we understand, in a second printing; therein doubtless several minor printer's errors will have received attention. The chief, if not the only serious, defect of the first edition will also, it is hoped, be put right. It is obvious from internal evidence that a very long time must have elapsed—long, anyhow, in relation to the rapidly changing circumstances of to-day—between the author's completion of his manuscript and the publication of the book. Thus, Table I contains no analytical data for national bread (only for white and for wholemeal), while banana and orange are both included in that table. It is also a pity when publishers, expert in catering for their own general or specialized publics, should presume to knowledge about the requirements of other publics, and then show themselves lacking in this knowledge; the publications of the Left Book Club or of Miss Dorothy Sayers can generally, if not always, dispense with an index, but its removal from Prof. Marrack's manuscript (wherein he must certainly have included it) has almost fatally affected the book's permanent utility, especially as it covers the whole of the very wide field over which those interested in human nutrition must to-day cast their eyes. Prof. Marrack ranges easily and lucidly from the structural formulae of pure vitamins to the less obvious implications of food control, from the conditions that produce deficiency diseases to the planning of agriculture in the post-war world.

Everywhere the author's common sense—sometimes, moreover, expressed with an attractive pungency—makes itself felt. This is a book that will be enthusiastically welcomed by the level-headed reformer and even by the intelligent revolutionary, but will give poor comfort to the food crank or to the defeatist. Prof. Marrack knows what we all need, and shows how it can be got; he does this, however, without in any way minimizing the difficulties that may have to be overcome.

The book begins with a chapter that constitutes a general introduction to the physiology of nutrition—so excellent an exposition as to make unjustifiable the continued publication of many of the numerous cheap booklets in which predigested nutritional science is gingerly dropped into the intellectual mouths of John (and Jane) Citizen by our more dietetic-minded guides, philosophers, and friends. The author's next two chapters are on food requirements and the effect of deficiencies on growth. The first chapter and these two might well be reprinted separately as the "Intelligent Woman's Guide to Social Feeding." The addition of Chapter IV, in which the nutritive value of different foods is considered in detail, would provide her with practically everything she need know about the principles of a scientifically based diet, whether for herself in pregnancy and lactation, the newborn infant, the growing family, the wage-earner, the school dining-room, the factory canteen, or the British Restaurant.

The next part of Prof. Marrack's book surveys what people actually eat (Chapter V) and the relation between health and the food that different groups have been found to consume (Chapter VI). The remaining six chapters contain, among other things, a most interesting survey of rationing during the last war, and may remind many readers of things that they have forgotten—perhaps subconsciously urged to this forgetfulness—of which they would be glad to be reminded when considering the problems of this war and its sequelae. There are, further, two chapters concerned particularly with war problems—one on war and health and the other on planning during scarcity—as well as an examination, in so far as available data permit, of the present position in Britain, Germany, and some other countries. Finally, Prof. Marrack has given us his views on the changes that will be needed if we are truly to plan for plenty; he is clearly of the opinion that this must involve restrictions both of national sovereignty and of private enterprise, especially of the latter, though the two cannot be separated.

It would be unfair, because misleading, to refer to the small number of *obiter dicta* that seem to call for some qualification. Any book of as wide a range, written with an equally genuine sincerity and tempered anxiety, must furnish examples of such casual comments. Perhaps, however, one may be permitted once more to point out the unfair implication usually conveyed by authors who refer to rickets as "the English disease." Prof. Marrack is among those who have managed to give the impression that this phrase was coined on the Continent because the condition was characteristic of these islands, whereas it was, in fact, so called because Glisson gave the first complete description. It was in honour of British medicine, not as a reproach to our climate or diet, that rickets got its association with this country. Again, the implication of a remark on p. 71 is that all dried milks, because they have been dried, require an antiscorbutic supplement for infant feeding. The truth, of course, is that all cows' milk (and many breast milks) should be so supplemented, whether raw, pasteurized, boiled, condensed, evaporated, or dried. On the other hand, one cannot write too strongly in support of Prof. Marrack's wise words about the so-called "protective" foods: his remarks are well worth quoting.

> "There has sprung up also a kind of snobbish attitude to foods, which are divided into an aristocracy of 'protective foods,' a middle class of 'body-builders,' and a lower class of 'workers and warmers.' In the first place, it is rather absurd to regard foods that supply vitamins as specially 'protective.' A man will die in a few days if deprived of water, and in a few weeks without any food, but can last for months without protein or vitamins. As far as 'protection' goes, water comes first, calories second, vitamins and proteins also run. And what foods, apart from sugar and perhaps unfortified margarine, do not contribute some vitamin or body-building substance?"

From among the growing pile of books under which the bookshelves and desk of the nutritional reviewer are slowly being submerged there is none that provides a more level-headed view of the present position or a saner appraisement of the problems lying in wait for those who wish to go forward on the basis of "sufficiency for all before abundance for some."

NEUROSURGERY

The Principles of Neurological Surgery. By Loyal Davis, M.S., M.D., Ph.D., D.Sc. Second edition, thoroughly revised. (Pp 503. 35s.) London: Henry Kimpton. 1942.

The author modestly claims that this book places before the practitioner the possibilities of neurosurgery, leaving out technical detail and the intricacies of neurological theory, but drawing attention to the chance of therapeutic relief in many conditions which formerly have been considered hopeless. Actually it achieves much more than this, for in the wide field it covers it sets forth a well-balanced summary of the majority opinion of neurosurgeons at the present day.

It is intended principally for the general practitioner and the undergraduate student, but we suspect that the latter may find it difficult to distinguish between matters of primary and secondary importance, since the book is written in the style of a monograph rather than that of an elementary textbook, and the absence of the cruder forms of sign-posting may be a handicap. To the student who is prepared to make his own abstract it offers a mine of information which will amply repay his industry.

In addition to a comprehensive review of intracranial disease there is an excellent account of peripheral nerve injuries and of the surgery of the sympathetic system, including an assessment of the modern treatment of arterial hypertension. In all sections adequate reference is made to recent literature, and the author's personal experience is freely drawn upon to enhance the practical value of the work.

Notes on Books

The 75th annual volume of *Whitaker's Almanack,* for 1943, has now appeared in three forms—library edition, leather-bound with coloured maps, at 21s.; complete edition, cloth-bound, at 10s.; and a shorter edition, containing the first 704 pages of the full book, paper-bound, at 6s. One of its principal features is the increase in space given to Government and Public Offices, extending to 101 pages. The diary of the war is condensed into 16 pages, and "Government by Party," which appeared in the 1932 edition, is reprinted in the present issue, with an extension covering the past 10 years. Upwards of 30,000 index references are given, ranging from a single line to the classified summary of 250 entries for Scotland and 300 for the United States. The publishers ask us to state that copies of this almanack may not be available at once.

The second edition of Dr. ARTHUR J. AMOR'S *X-ray Atlas of Silicosis* has only one change in its contents—a reference to the work of D'Arcy Hart and E. A. Aslett in their survey of chronic pulmonary disease in South Wales miners. The production of a second edition two years after the first is in part due to destruction of some of the first edition by enemy action. New blocks have had to be made of many of the original illustrations, and in spite of current difficulties their quality has been maintained and, in a number, improved. The reappearance of this valuable monograph is to be welcomed. It is published by John Wright and Sons of Bristol at 30s.

The *Annual Charities Register and Digest* for 1943 has just been published by Longmans, Green and Co for the Charity Organization Society. This is the fiftieth edition of a very useful reference book which provides information concerning the societies, associations, and other bodies that provide relief in all kinds of affliction and distress. It contains the same number of pages as last year, and gives details of more than 2,700 institutions and societies. Copies can be had from the C.O.S., Denison House, 296, Vauxhall Bridge Road, S.W., or from the publishers (8s. 6d.).

In reviewing the first edition of *The Design of Experiments,* by R. A. FISHER, Sc.D., F.R.S., we expressed the opinion that it was one of the most important contributions to methodology of our time. We see no reason to vary this opinion and are glad to see that, even in these times, a new edition is required, the third in six years. A book like this cannot be easy reading, and its success is good evidence that intelligent persons are increasingly interested in the statistical control of experiments, so that the maximum of information may be had with the least expenditure of time and money. The publishers are Oliver and Boyd, and the price is 12s 6d.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY FEBRUARY 13 1943

THE B.M.A. AND THE BEVERIDGE REPORT

In spite of their many professional preoccupations at a time of year when sickness in the civil population makes unusual demands on a doctor's time even in peace, the various committees of the Association have been hard at work studying the Beveridge report, and in particular Assumption B: "Comprehensive health and rehabilitation services for prevention and cure of disease and restoration of capacity for work, available to all members of the community." At its meeting on Feb. 3 the Council of the B.M.A., the proceedings of which are reported in this week's *Supplement*, had before it the recommendations of the committees, the chairmen of which in turn gave the Council some idea of the atmosphere in which discussions had been conducted. The Chairman finally put before the Council a motion for its consideration and ultimate transmission in the form of a recommendation to the Representative Body. The motion was so framed as to embody the sense of the recommendations of the several committees. It was closely examined, and alternative readings of most of the sentences were considered, before the final form was adopted.

> "That it be recommended to the Representative Body that if Parliament, after consideration of the Beveridge report, decides to accept the assumptions of the report and to put into operation the proposals of the report, taken as a whole, including a scheme for comprehensive health and rehabilitation services for prevention and cure of disease and restoration of capacity for work, available to all members of the community, the Association would be willing to co-operate in the preparation of such a scheme provided—
>
> (*a*) That the character, terms, and conditions of the medical service are determined by negotiation and agreement with the medical profession; and
>
> (*b*) That those members of the community who decide not to avail themselves in part or in whole of the benefits of the service open to them should not be precluded from obtaining the medical services they desire from doctors within the scheme, paying for such service privately, with the necessary safeguards to prevent abuse."

This recommendation will be considered by a special meeting of the Representative Body and of the Panel Conference, and by a joint meeting of the two, at the end of March. Between then and now the Divisions will consider the Council's recommendation, and it is hoped that as many members as possible will attend their Division meetings.

The first point to be noticed in the recommendation is that co-operation is offered on the ground that Government action is taken on the report as a whole. This is fundamental. In the first place the Government might offer a sop to the public by putting into effect only the proposals for a medical service. But this service cannot be considered apart from the context of the report, as the medical profession is closely concerned with the health aspects of Sir William Beveridge's attack on want and idleness, the removal of which by his plan would be a public health measure of the first importance. So, although the medical profession must concentrate on Assumption B, it cannot shut out from consideration the report as a whole. In deciding what its attitude to this should be and to the medical implications in it, doctors should keep clearly in mind one factor, and that is the wide public interest in the problem of social security and the growing public desire to see that after this war such security is obtained. No Government, we believe, could afford to let such conditions arise as fostered the bitterness, disillusion, cynicism, and apathy that were the sour fruits of the victory of 1918.

The medical implications of Sir William's Assumption B are contained in the following two sentences from the report: "From the standpoint of social security, a health service providing full preventive and curative treatment of every kind to every citizen without exception, without remuneration limit, and without an economic barrier at any point to delay recourse to it, is the ideal conception. It is proposed accordingly that, in the contributions suggested as part of the plan for social security, there shall be included a payment in virtue of which every citizen will be able to obtain whatever treatment his case requires, at home or in an institution, medical, dental, or subsidiary, without a treatment charge."

That the whole resources of modern medicine should be at the disposal of every man, woman, and child in the country is a proposition to which every doctor naturally assents. That at some times, and in some places, various lets and hindrances prevent some citizens from taking full advantage of these resources cannot be denied. But neither can it be denied that all the time continuous efforts are being made by official and private agencies to fill the gaps that exist, to co-ordinate and unify services, and to facilitate the practical application of new knowledge and technique. There has been general acceptance of the B.M.A.'s proposals that the scope of national health insurance should include consultant and other services, and be extended to the dependants of insured persons. In other words, the idea of a complete service on a compulsory insurance basis is already accepted by the medical profession for roughly nine-tenths of the population. The Beveridge proposal is that such a service should be available to the whole population, rich and poor alike. The medical profession in Great Britain has to make up its mind what its attitude to this proposal is to be.

Upon what grounds could the medical profession oppose the complete acceptance of the Beveridge proposal? It is certain that if it is put into operation it will affect the private practice of all doctors and will affect adversely the incomes of some doctors. But could the medical profession hope to oppose the Beveridge plan successfully on the ground of finance? A more formidable argument against the plan is that the creation of a service open to the whole community might lead sooner or later to a whole-time salaried State service, and to this the majority of the doctors in this country are at present resolutely opposed.

But the "100% proposal" does not necessarily imply a whole-time State salaried service. If it did, the Council of the B.M.A. would have advised the Representative Body to reject it. It would, however, be quite another matter to advise the rejection of the proposal that the State should make available for every member of the community a comprehensive health and rehabilitation service.

Whether the compulsory insurance scheme should cover 100% of the population, or only, say, 85 to 90%, is a matter which Parliament has not yet decided or even discussed. Whatever the people of this country, through their representatives in Parliament, may decide on this issue of coverage, it would be undemocratic, not to say foolish, for the medical profession to run counter to the rest of the community at a time when it needs all its sympathy and support in what is the gist of the matter—namely, determination of the conditions and terms of service. The Council advises co-operation, with the important proviso that the character, terms, and conditions of the service must be negotiated with and agreed by the doctors of this country. And the doctors of this country do not believe that it is in the public interest that the medical profession should be turned into a whole-time salaried civil service, with the doctor the servant of the State. The doctor must be the servant of his patient.

In the past the medical profession has too often found itself fighting a rearguard action. Here, it seems, is an occasion when the medical profession can take a forward-looking view on a matter of the first importance, and this without sacrificing any of those professional principles upon which the practice of medicine is based.

AETIOLOGY OF LUNG CANCER

There has been an alarming increase in the amount of lung cancer diagnosed during the past twenty years. To describe the increase as one in diagnosed cases is important, because improved diagnosis accounts for much of the apparent difference in incidence between present and past; the clinical picture of this disease is not unmistakable, and in the absence of radiological or post-mortem facilities many cases must have gone unrecorded. Nor is it safe to deduce an absolute increase from the experience of any single institution. As Passey has pointed out, largely increased numbers of cases have been recorded from hospitals to which a tuberculosis dispensary is attached, for the evident reason that doubtful cases reach them from a wide area through this channel, while at other hospitals it may be a policy not to admit incurable cases, and there in-patient and post-mortem figures for the disease will be correspondingly low. When these sources of error have been eliminated, and allowance is made for the longer life of the average individual, there nevertheless remains an increase in the frequency of lung cancer which is considered by most authorities to be absolute. It is natural to seek the cause of this in some condition of modern life, and particularly among materials which may be inhaled, since nothing in connexion with cancer is better attested than the local carcinogenic effect of long-continued application of certain "irritants." Tar, certain lubricating oils, soot, arsenic, and various radio-active substances will cause epithelioma of the skin; the long-continued inhalation of any such substance may well produce cancer of the lung. That in the Schneeberg and St. Joachimstal miners' cancer we have a clear example of this effect there is no doubt, but the frequency of the disease among these miners is exceptional, as is the composition of the dust to which they are exposed. It is of greater interest to inquire whether other materials in air to which much larger numbers of people are exposed can have a similar if less pronounced effect. This question can be approached in two ways, of which one is to ascertain the incidence of the disease in occupational classes. Evidence has in fact been extracted from the Registrar-General's returns that lung cancer is commoner in certain occupations. The other method is experimental. It is of course well known that actively carcinogenic substances will produce lung cancer as well as tumours elsewhere, but to obtain evidence bearing more directly on the human disease it is necessary to expose animals to atmospheres containing dust or other supposedly carcinogenic materials on which suspicion has fallen. This is a singularly tedious form of experiment, requiring the utmost patience if the necessary conditions are to be fulfilled.

Such a study has been pursued for ten years by J. Argyll Campbell, whose principal findings are recapitulated and discussed at p. 179. He has been able to show that a variety of dusts, natural or prepared, will increase the frequency of lung tumours in mice, sometimes to a very marked degree. He also advances reasons for regarding these findings as applicable to man. It may perhaps assist judgment on this matter to state the particulars in which the mouse and human tumours differ. The first and most obvious is that lung tumours are exceptionally common in some strains of mice; their incidence in control animals in some of these experiments was 20%. No other animal behaves in this way, and innumerable dusting experiments conducted for the study of silicosis have not been found to produce lung growths in rabbits, guinea-pigs, or rats. The tumour itself in the mouse is usually an adenoma, in which malignant change is the exception. It is true that bronchial adenoma is gaining increased recognition as a common human tumour, but in both site and age incidence it differs from the mouse tumour, while of course it may be held to stand apart from primary lung cancer, the disease with which we are mainly concerned. On the other hand, when lung tumours are produced in mice by actively carcinogenic hydrocarbons they usually take this form, and the mouse adenoma, when it occurs with unexpected frequency, may therefore rightly be regarded as a response to a carcinogenic stimulus. Another aspect of this subject on which finality of conclusion would perhaps be premature is the position of silica. Whether silicosis itself or the inhalation of siliceous dust predisposes to cancer of the lung has been hotly debated. The weight of evidence seems to point to a negative answer, in particular the very imposing figures collected by A. J. Vorwald and J. W. Karr.[1] Campbell's findings, on the other hand, incriminate this agent, both in experiments with pure silicon dioxide and by implication in experiments with road dust, the extraction of which with benzene in order to free it from tar reduced its capacity to stimulate neoplasia, but did not abolish it. It should be mentioned that the validity of this conclusion has been questioned by A. Kling *et al.*[2] on the ground that extraction with benzene does not entirely remove the carcinogenic constituents of tar from dust; minerals are said to absorb tar and part with it reluctantly. They themselves made an artificial mixture of 100 parts of powdered stone, as used for road metal, with 1 part of tar, and after extracting with benzene until this solvent removed nothing more, they treated the powder successively with sulphuric ether, and acid and alkaline alcohol; in all three of these solvents they could demonstrate benzpyrene. This is therefore one of several aspects of a difficult subject upon which some doubt remains. A general belief that some forms of atmospheric pollution may be a factor in producing lung cancer is well justified, and some constituents, notably tar, are more suspect than others. How seriously to regard non-tarry dusts, soot, exhaust gases, and tobacco smoke is a question to which the present answers can only be provisional.

WASTING DISEASE AND LESIONS OF THE NERVOUS SYSTEM

The probability of an increased incidence of wasting disease and dietary deficiency in Europe makes a recent contribution from China of particular interest. Hypovitaminosis in man may result from inadequate intake, faulty absorption, excessive loss, or a requirement increased by heightened metabolism in febrile disease, all factors which are known to be prevalent in China. Hsü[1] carried out a very thorough histological examination of the central nervous system in 13 subjects who had died from wasting disease associated with dysentery and tuberculosis. In every case distinct lesions of the intestine were demonstrated. The changes in the nervous system were remarkably uniform in nature, including primary irritation of the Betz cells, and degeneration of the dorsal spinal ganglia, posterior columns, posterior nerve roots, and peripheral nerves. In beriberi peripheral nerves are primarily affected, while in pellagra the brain appears to be the earliest site of disturbance. The symptoms of vitamin-B deficiency were recorded in only one case, but it is possible that these manifestations had been overlooked in the others. The author, indeed, after an exhaustive search of the literature and analysis of his own findings, has come to the conclusion that the combination of pathological changes points to deficiency of the vitamin-B complex. Whether or not this is the case, it raises the interesting problem of the organic basis for the neurological abnormalities that arise in the course of general diseases. The association between disorders of the alimentary tract and disease of the nervous system has long been suspected. Hsü stresses the importance of an exhaustive neuropsychiatric examination in all those showing disturbances of the gastro-intestinal system. It must be left to experimental work to decide whether disease of the alimentary tract acts directly on the central nervous system, presumably by cutting down some hormonal effect or indirectly by impairing the absorption or utilization of one of the vitamins. Meanwhile, it might be wise again to emphasize the importance of adequate vitamin intake for all patients with digestive disorder.

THE EPIDEMIOLOGY OF STREPTOCOCCAL INFECTIONS

Of three great advances made during the past twenty years in the study of streptococcal infections two have been American and one a British achievement. The Dicks of Chicago elucidated the relationship of *Str. pyogenes* to scarlet fever, and thus provided the means for its specific treatment and prevention. Lancefield applied the precipitin test to the classification of this organism, and thus furnished a ready means of identifying strains as potentially dangerous. More detailed antigenic analysis, a task beset with difficulties which defeated other workers, was carried to fruition by the late Frederick Griffith, and resulted in the definition of about 30 types, nearly all included in Lancefield's Group A, which are now inseparable from his name. Thanks to the labours of Griffith himself and others whom he instructed in his methods, this country has led the world in studying the epidemiology of haemolytic streptococcal infections. Only by typing has it been possible to prove the source of cases of puerperal fever, to trace the origin of milk-borne scarlet fever, and to follow the migrations of streptococci in epidemics with such various manifestations that they had previously gone unrecognized. That the same streptococcus may successively cause in different individuals tonsillitis, scarlet fever, erysipelas, simple wound infections, an almost symptomless throat catarrh, otitis media, and, if opportunity occurs, puerperal fever, is now generally recognized. Any of these manifestations may be produced in certain circumstances by any streptococcus of Group A, with the single proviso that the rash which alone differentiates scarlet fever from other streptococcal throat infections will develop only if the streptococcus is of one of the types which form the erythrogenic toxin, and then only if the patient is susceptible to that toxin. This knowledge has made plain much that was obscure before, but in the recognition of ward and other epidemics and in devising precautions to check them there is still much to be done in applying it.

The typing of streptococci was for some years a British prerogative, but it has now found its place in the United States, and C. S. Keefer and his colleagues[1] describe a study made in Boston in which 819 strains from various sources were examined. Agglutinating sera were available for 19 of Griffith's types, and served to identify all but 180 strains. The types most commonly encountered were 1, 11, 13, and 15, but, although their frequency distribution doubtless varies in different countries, no conclusions on this should be drawn from any single study: the chance occurrence of epidemics embraced in it will exaggerate the numbers of that type to a figure not representative of a wider area or a longer period. Analysis of the infections caused by each type shows no special organ predilection, or any association between type and a particular lesion such as erysipelas. It was found that when multiple infections occurred in households or institutions, however various their nature, they were usually due to a single type and often traceable to a single individual. The inclusion of many cases of scarlet fever enabled the authors to study the effects of reinfection with a different type of streptococcus during the course of this disease, an occurrence now known to be common in fever hospitals. When a complication such as otitis media occurred early in the disease, the type was usually unchanged; when it developed after the fifteenth day it was unchanged in only 2 cases and different in 16. Two cases of recurrent scarlet fever were both associated with a change of type. Here and in many other of the varied aspects of streptococcal activity the serological method supplies an explanation obtainable in no other way.

ANTI-SOCIAL BEHAVIOUR DISORDERS

Most medical men are familiar with the admirable work of the Chadwick Trust in furthering preventive medicine, and the trustees did wisely when they recently instituted a lecture on the differentiation, prevention, and treatment of anti-social behaviour disorders. Such ills are not often regarded as within the scope of State medicine, but they menace the health of the community quite as gravely as do venereal disease or typhoid fever. As Dr. W. Norwood East, the lecturer, said in his opening remarks, Sir Edwin Chadwick, who acted as Jeremy Bentham's secretary for the last three years of Bentham's life, must often have discussed with the philosopher-jurist the causes and treatment of anti-social behaviour, for they were both interested in the subject. In general terms, said Dr. East, such disorders result from stress acting upon an innate constitutional pattern which is modified by environmental factors. Social reactions are closely related to the desire for security and satisfaction, the achievement of pleasure, and the avoidance of pain. In the ordinary affairs of life behaviour is related to both proximate and distant aims. In strong and harmoniously organized characters whose reactions are well balanced, short-term satisfactions are useful as occasional stimuli which assist them to realize long-term ideals. It is characteristic, on the other hand, of much anti-social disorder that the desire of the moment is more importunate and decisive than a long-term ambition. Disordered behaviour associated with insanity is rarely criminal: less than 1% of persons admitted to prison are insane. The anti-social behaviour of many of these could have been avoided by early medical advice and treatment. Similarly, much anti-social behaviour due to mental deficiency can be prevented if the mental condition is ascertained early and there is effective supervision. Anti-social behaviour associated with neurosis is characterized by its emotional content, which partly depends upon mental conflicts. The most important corrective factor is, perhaps, early recognition. Since the social difficulties of the psychopath are largely due to apparently innate factors, anti-social behaviour disorders in this group are often not easy to prevent. Treatment may be unavoidably restricted to modifying the particular activity which is adversely affecting the behaviour. Child guidance clinics, by recognizing those influences in the child which give rise to unusual behaviour, can often prevent future behaviour disorders. Critics of the methods of Government Departments might do well to study more closely the industry and bold readiness to experiment which the Home Office authorities constantly show in their struggle against delinquency and crime. Dr. Norwood East hopes that the Criminal Justice Bill of 1938 will be revived as soon as the war is over, and declares that the stepping-stones laid down by scientific research workers must be used; for, he argues, in a democratic State we cannot afford to ignore the effect upon each one of us of social hazards which are harmful and preventable. He had already observed in dealing with child guidance that the materialism and determinism of past years are being displaced in many directions by a spiritual approach to some of life's problems which is independent of science. Social historians of the future will be able to judge whether reforms such as the Beveridge plan, which will presumably remove a good deal of the insecurity which is an ingredient in behaviour disorders, have contributed at all towards reducing anti-social behaviour. It may be doubted whether greater material prosperity will produce a better society unless that society is welded by aims and beliefs that are not material.

EXPERIMENTAL TUBERCULOSIS

The role of genetic constitution in determining resistance to tuberculosis is even now not well understood. There are so many variables. Massive infection can overwhelm naturally good resistance, and other factors of a non-genetic character can reinforce or nullify the advantages or disadvantages with which the child may have been born. It is not surprising, therefore, that so much remains mysterious or controversial; but what is surprising, perhaps, is that more use has not been made of animal experiments. This omission lends special interest to the contribution of M. B. Lurie of the Henry Phipps Institute of the University of Pennsylvania (assisted in some observations by P. Zappasodi), who has presented[1] a detailed account of seven years' careful work on rabbits. Six families were used, close inbreeding being practised, and it was found that under uniform environmental conditions there were notable differences in resistance between the families. These differences could be demonstrated by measuring survival time after a parenteral standard dose of tubercle bacilli; after inhalation of known numbers of bacilli in a specially designed apparatus; or after natural respiratory contagion. It was noteworthy that, using the first two methods, the differences could be abolished by sufficiently massive dosage. Under natural conditions of infection—which, it is suggested, are similar to those occurring in man—the rabbit families fell into three groups, and the pulmonary tuberculosis acquired, generation after generation, had the essential features of the disease as manifested by different racial groups of human beings.

After natural respiratory contagion rabbits of the resistant family acquired a tuberculosis of long duration, usually originating in a single, slowly progressive, encapsulating primary focus which became excavated. The draining tracheo-bronchial glands did not become involved. The disease was confined chiefly to the portal of entry, the lungs, where it spread from the softened primary lesion and where the secondary foci progressed in a similarly chronic manner. There was little dissemination to the rest of the body, and in the few instances of pulmonary haematogenous dissemination the tubercles did not thrive. The disease was essentially a localized ulcerative pulmonary phthisis analogous to the reinfection type seen in white adults. Microscopically, it was found that only in caseous foci undergoing softening did the bacilli accumulate in any considerable numbers. The disease extended only by the aspiration of bacillus-laden softened material into preformed channels, the high natural resistance of the tissues being thus overcome by flooding with vast numbers of organisms. What is probably of fundamental importance is that the mononuclear phagocytes of this family acquired the capacity to inhibit the growth of tubercle bacilli in their cytoplasm.

Rabbits of the susceptible families presented a very different picture. The disease also originated as a single primary focus in the lung but rapidly progressed without encapsulation or excavation. The draining glands became massively enlarged and caseous, and widespread blood dissemination then took place. The disease was a primary, rapidly progressive, generalized tuberculosis simulating the so-called childhood type in man and resembling the rapidly fatal form observed in Senegalese troops. Microscopically, tubercle bacilli were seen to swarm in the mononuclears, and blood vessels underwent necrosis *en masse.* Secondary lesions were equally rapidly progressive. In one family, what were apparently factors favourable to resistance were overcome by a particular vulnerability of the blood vessels to bacillary invasion. The rabbits belonging to some families were intermediate in their behaviour, and it is suggested that in them the course of the disease resembled types observed in the American negro. Essentially, resistance seemed to depend on the completeness and rapidity with which the tissues acquired a local immunity. There was also some evidence of an association between high resistance and low skin permeability, the rapid and intense development of allergic sensitivity, and the rapid production of antibodies.

It is good to know that these valuable studies are being continued. One point, for example, which may be elucidated is the number of bacilli forming the unit of infection which is responsible for the single primary focus in the rabbit, and also perhaps in man, for when the inhalation apparatus was used, even with relatively small numbers of bacilli, there were always multiple foci proportional to the dosage.

The next session of the General Medical Council will open on Wednesday, Feb. 17, at 10.30 a.m., when the President, Mr. H. L. Eason, will take the chair.

Reports of Societies

PRINCIPLES OF ANATOMY AND THE PERIPHERAL NERVES

At a meeting of the Section of Physical Medicine of the Royal Society of Medicine on Jan. 13, with Dr. PHILIPPE BAUWENS in the chair, Prof. H. A. HARRIS of Cambridge University, who was to have given an address under the title "The Anatomical Basis of Physical Medicine," said that since choosing his subject he had received the Medical Research Council War Memorandum No. 7, *Aids to the Investigation of Peripheral Nerve Injuries,* and it occurred to him that it might be of some advantage to consider to what extent the principles of anatomy were exhibited in this most recent publication.

The development of the limb bud in the human embryo began, he said, towards the end of the first month of embryonic life as a raised papule in the neck region and emerged as a mitten-shaped projection for the hand; a few days later the wrist was in sight, to be followed in turn by the forearm, elbow, arm, and shoulder. The two surfaces of the limb were distinct, the flexor muscles with their fine movements covered with hypersensitive and pliable flexor skin, the extensor muscles with their coarse movements covered by skin relatively less sensitive and tougher. As far back as 1885 there was intensive study of the morphology of the nerve plexuses of the limb by such men as Herringham, Paterson, Head, and Sherrington. It was Herringham in particular who stated that the nerve supply of the limbs was fundamentally segmental. He maintained that the skin of the limb was stretched like a sheet of rubber over the limb, that the extensor area was greater than the flexor area, and that the central nerve of the plexus only emerged on the skin surface at the periphery. He held that although the lower four cervical nerves and the first thoracic nerve constituted the basic five nerves of the brachial plexus, yet some skin had been borrowed from adjoining segments or dermatomes.

In the lower limbs the plexus was fundamentally formed from the last two lumbar nerves and the first three sacral, but as a result of the great development of the buttock and thigh, skin had been borrowed extensively from the adjoining segments or dermatomes at the pre-axial border. This borrowing was limited to the pre-axial border and could not take place at the post-axial border, as this lay "next door" to the territory of the fourth sacral nerve in the perineum in general and in the anus in particular. In the skin of the lower limb, not only were areas supplied by the adjoining dermatomes of the first three lumbar segments, but an area extending from the iliac crest to the great trochanter of the femur was supplied by the lateral branch of the twelfth thoracic or subcostal nerve.

Segmental Nerve Supply of Skin

Herringham paid great attention to the analysis of the typical segmental nerve, its posterior primary division for the skin and muscles of the back, its anterior primary division for the skin and muscles of the body wall, and particularly the lateral branch of the anterior primary division which supplied the flank. The limb bud always developed in the territory of the lateral branch of the anterior primary division of the segmental nerve. If the body were placed with the limbs in the embryonic position of flexion with the thumb and great toe towards the head, palm towards palm and sole towards sole, the pre-axial and post-axial borders of the limb gave the key to all the main points in the cutaneous supply to the limbs. In the upper limb the pre-axial and post-axial borders were marked out roughly by the cephalic and basilic veins; in the lower limb by the great saphenous and the small saphenous veins. Herringham stated that of two spots on the skin of the limb that nearest the pre-axial border tended to be supplied by the higher nerve. Of two spots on the pre-axial border the lower tended to be supplied by the lower nerve, but of two points on the post-axial border the lower was supplied by the higher nerve. Herringham went further, and pointed out that on the ventral and dorsal surfaces of the limb there was a hiatus in the numerical sequence of the nerves, explicable on the ground that the central nerves of the plexus, which failed to reach the surface in these situations, were replaced by cutaneous branches from neighbouring nerves. This gap or hiatus was the axial line.

These classical descriptions by Herringham were in part envisaged even as early as 1857 by Sir John Goodsir, professor of anatomy in Edinburgh a hundred years ago, for he recognized that the higher or pre-axial nerves in the plexus did not run as far into the limb as the lower or post-axial nerves.

Nerve Supply of Muscles

The principles which worked so well for the nerve supply of the skin had their counterpart in the segmental nerve supply of the muscles. Muscles near the pre-axial border, such as the deltoid, would be supplied by the higher nerves, the fifth and sixth cervical, whereas muscles near the post-axial border, such as the flexor carpi ulnaris, would be supplied by the lower nerves, the eighth cervical and first dorsal. In the upper limb all the muscles were supplied by the five basic nerves of the plexus, and there was no borrowing of muscle and nerve from the adjoining segments. On the other hand, in the lower limb, on account of the extensive growth and development of the buttock and thigh, the nerve supply of the muscles was not limited to the five basic nerves, from the fourth lumbar to the third sacral. The nerves and muscles of the adjoining pre-axial second and third lumbar segments had been brought in to provide the muscle and nerve which, with the fourth lumbar segment, constituted the quadriceps mass and the main part of the adductor mass, supplied respectively by the femoral and obturator nerves.

Herringham emphasized the segmental character of the nerve supply to muscle and insisted on the greater complexity of the flexor muscles as compared with the extensors. This complexity was reflected in the fact that the nerves of the flexor compartment were more numerous than those of the extensor compartment. The additional nerve of the flexor compartment was always post-axially placed. In the upper limb the posterior cord supplying the extensor mass was supplied by the lower four cervical nerves only, but the flexors were supplied in addition by the first thoracic nerve, which was post-axially placed, and practically all its fibres were in the ulnar nerve. Similarly, in the lower limb, the extensor mass was supplied by the nerves ranging from the second lumbar to the second sacral, but the flexor mass was supplied also by the third sacral, post-axially placed, in the nerve to the biceps femoris.

Prof. Harris maintained that the recent M.R.C. report showed but little evidence of acquaintance with the clinical implications of the work of Herringham on the morphology of the nerves to the skin and muscles of the limbs. It showed also little evidence of our knowledge of the classification and actions of muscles as established by Winslow, John Hilton, Duchenne, Charles Beevor, and Sherrington. The editions of Quain's *Anatomy* and of Cunningham's *Text Book of Anatomy* published at the beginning of the century had not neglected the importance of these anatomical principles. Modern textbooks had shown a tendency to do so.

The Stretched Nerve

A correspondence had recently taken place in the *British Medical Journal* concerning new and unnecessary names for certain objective and subjective phenomena in relation to nerve injuries. With regard to nerve injury the thing which mattered most was the stretching of the nerve or interference with its blood supply. Everyone was familiar with "pins and needles" of the leg and foot, a vascular phenomenon, but the stretching of a nerve was a more serious matter because recovery might not follow. For this reason it was worth while considering the many nerves in the body which were in such a position that they were liable to be injured as a result of stretching in various occupational injuries.

One common symptom was found in people working a lever when, instead of depressing it with the hand as a whole, they used only the hypothenar eminence to bang the lever down. They injured the ulnar nerve between the pisiform and the hook of the unciform bone. Similar trouble arose from working with the elbows pressed on a work bench with an upturned edge like a tea-tray. The ulnar nerve was rubbed on the coronoid process of the ulna and palsy resulted. Prof. Harris demonstrated by means of a skeleton the number of bends in the course of the ulnar nerve which went down the length of the arm. The fibres of the first thoracic nerve in the ulnar were stretched over the neck of the first rib; the ulnar nerve was stretched at the medial condyle of the humerus, and again as it passed around the hook of the unciform. Similarly those fibres of the fourth lumbar nerve which joined the sciatic presented sharp bends on emerging outwards from the intervertebral foramen, passing downwards in front of the sacro-iliac joint, backwards through the great sciatic foramen, and again outwards almost to the anterior superior iliac spine in the course of the superior gluteal nerve to glutaeus medius and minimus and tensor fasciae femoris. Another nerve, the sixth cranial, was in such a position that any disturbance of the brain or the cerebrospinal fluid was liable to stretch it, giving the transient palsies seen after slight accidents. The first thoracic, the fourth lumbar, and the sixth cranial nerve "lived dangerously," and were perpetually on the verge of a breakdown.

He also referred to the diagrams customarily given to show the tendon sheaths. A tendon sheath was grown where it was wanted. It made its appearance in response to the range of movement. The same with bursae. These would be grown where they were wanted, either in response to movement or to pressure, or because of ill-fitting footwear or unaccustomed work. The arrangement and extent of the flexor synovial sheaths in the hand were determined by the range of movement of the metacarpal bones and overlying tendons. This was maximal in the mobile metacarpal of the thumb with a continuous synovial sheath, next greatest in the mobile metacarpal of the little finger, and least in the rigid metacarpals of the index and middle fingers. He believed that the principles of anatomy were there for whoever wished to seek them; the monstrous burden of endless detail now placed upon the student was entirely due to the fact that teachers would not recognize that principles were designed to save time, to avoid useless memorizing, and to provoke further thought. In anatomy, as in other subjects, it was well worth while occasionally to pay heed to one's grandfather, because he might have acquired not only facts but certain valuable working hypotheses or principles.

SMALL-POX IN SCOTLAND IN 1942

At a meeting of the Section of Epidemiology and State Medicine of the Royal Society of Medicine on Jan. 22, with Dr. J. D. ROLLESTON in the chair, some aspects of the epidemiology of small-pox outbreaks in Scotland in 1942 were discussed.

Dr. IAN SUTHERLAND, having first mentioned two earlier epidemics in Scotland—one in Glasgow, a major small-pox epidemic in 1920-1 which caused 176 deaths, and the other in Dundee, a minor epidemic in 1927-8 which caused no deaths—said that there arrived at Glasgow on May 29 last year a ship with a case of major small-pox on board. The source of infection was a mystery. The man might have been infected while ashore at Capetown, or on board from a missed case, but no small-pox was known to exist at Capetown at the time the boat was there, and there was no other case on board with a rash. An electrical engineer occupied the same cabin as this first case and looked after the man, but he did not get small-pox; he went, however, to repair a potato-peeling machine for the assistant cook, and the assistant cook subsequently developed a small-pox eruption. In this outbreak in Glasgow there were 11 ship cases, 21 in the general population in which the source of infection was untraceable, and 4 in contacts. The "untraceable" cases were not scattered throughout the city area; the west and a large part of the south were free. Following the main wave of "untraceable" cases there were three or four secondary cases, including some persons who had little contact with the outside world and whose chances of acquiring a prevalent infection might be thought to be small. The range of ages in the "untraceable" cases was from 12 to 72. The last group included a patient in a mental hospital outside Glasgow who had been there for 14 years and had not had a visitor during the previous three weeks.

The epidemic in Fife apparently started with a patient whose rash appeared on August 21, and 26 subsequent cases were traceable to the original case or to secondary or derived cases. A general vaccination campaign was started in the district in October, a very large number of people accepting vaccination. Two further cases occurred in November, one of them "untraceable." No connexion was established between the Glasgow and the Fife outbreaks. Eight days after the last Fife contact case a man who was under the care of a surgeon in an Edinburgh hospital developed a small-pox rash, and this was followed by a small-pox rash in a boy and 3 students who had no connexion with the hospital patient, and in 16 patients of the same hospital and convalescent home, many of whom had been returned to their own homes before the outbreak declared itself. In the convalescent home the outbreak was baffling. The cases were confined to patients in one ward, about half of whom developed small-pox. The only connexions between the hospital and the convalescent home were the laundry and the interhospital ambulance, but investigation of these was negative. The next stage in the Edinburgh outbreak was the appearance of a group of 8 "untraceable" cases spread over 30 days in the general population. There was no feature of special interest in the social incidence, and no proof that the Edinburgh cases derived from the previous outbreaks. The disease was of a major type, with a fatality rate of 24%. Known contacts were always offered, and rarely refused, vaccination. General vaccination campaigns were started in Glasgow on June 30, in Fife on Oct. 3, and in Edinburgh on Nov. 18. Reviewing the range of clinical manifestations, the possibility of infection below the level of clinical recognizability could not be excluded without postulating any change in virulence; the existence of carriers remained speculative.

Dr. J. GLEN based his remarks on 35 cases which were admitted to Robroyston Hospital, Glasgow. There was evidence that a virulent infection was concerned; 64% of the cases were severe, including haemorrhagic and confluent cases. The routine treatment was as follows: 2 g. of sulphadiazine given 4-hourly day and night for 24 or 36 hours, followed by 1 g. 4-hourly for 6 to 10 days, typical cases receiving a total of 50 to 60 g. In addition 100 g. of ascorbic acid was given. In severe cases the eyes were irrigated with normal saline 2-hourly during the day and 4-hourly during the night. There were three groups of cases: (1) discrete small-pox in 18 cases, of which 6 were severe, none of which had been vaccinated; none of the discrete cases proved fatal; (2) haemorrhagic small-pox in 4 cases, 3 of them unvaccinated, and all were fatal; (3) confluent small-pox in 11 cases; 8 of these were unvaccinated, and in the 3 who had been vaccinated the vaccination had taken place 72, 37, and 13 years previously; 3 deaths occurred. No toxic complications were observed with the drug used.

Post-vaccinal Picture

Dr. PETER MCKENZIE said that in July, 1942, in Glasgow approximately half a million persons were vaccinated. Arrangements were made to concentrate any cases of encephalitis and vaccinal eruptions in one hospital. Fourteen cases were admitted as vaccinal encephalitis, and in 7 the diagnosis was confirmed. In no case did encephalitis follow primary vaccination in infancy; 6 of the 7 cases occurred in previously unvaccinated children between the ages of 2 and 16. The time of onset varied from 6 to 14 days after vaccination, and the duration of illness was from 5 days to 6 weeks; 2 of the children died, the other 5 recovered completely. In both the fatal cases there were rolling nystagmoid movements of the eyes with marked strabismus which varied from hour to hour. The arms were spastic and flexed, and on attempting to elicit nuchal rigidity a rough tremor developed in the forearms. Sections of the brain in the fatal cases showed a distinct zone of perivascular infiltration and oedema, with a suggestion of some lysis of the cerebral tissue in the part. More specialized neurological methods revealed that in the perivascular zones there had been obvious loss of myelin. During the epidemic period 3 cases were admitted to hospital which appeared clinically to be Kaposi's varicelliform dermatosis, characterized by the rapid appearance of pustules on the head, arms, and legs of a child already suffering from eczema. It was apparent in these 3 cases that the pustules in no way resembled varicella, but were indeed varioliform in character. All 3 patients were unvaccinated. He had been able to trace a further 7 cases of this condition which occurred in Glasgow during July and August, 1942. This was a rare condition, and the occurrence of a number of cases in relation to an outbreak of variola must be regarded as of some significance.

In further discussion Dr. GAUTIER (League of Nations Health Section) said that experience on the Continent had suggested that certain strains of lymph were more likely to give rise to post-vaccinal encephalitis. Dr. ANTONY DAVIDSON spoke of the good response of the Scottish public to vaccination, over one million persons having been vaccinated. He also referred to the capricious nature of the spread of small-pox, which made it the more difficult to control, and the increased difficulty in the clinical diagnosis of the disease in view of the fact that the long disappearance of this infection had left younger medical men unfamiliar with it. Col. WILLIAM BUTLER recalled the London epidemic of 1905, when it was found that vaccination given during the incubating period did not protect, so that it was a common experience to have vaccinia and small-pox concurrently, and these cases were more severe than the other features of the attack seemed to warrant. Sir LEONARD ROGERS urged that a declaration on the need not only for vaccination in infancy but for subsequent vaccination was required, and the Section passed a resolution in that sense. Dr. J. A. H. BRINCKER, after recalling an outbreak in Kent where secondary cases came out a couple of months later, asked whether they were sure that the cases of post-vaccinal encephalitis had nothing to do with the vaccine. Was it not possible that these cases might be due to a virus or some other form of infection latent in the individual, which the fact of vaccination was enough to set in action? Dr. E. A. UNDERWOOD said that there was a fair amount of evidence that post-vaccinal encephalitis was the precursor of some neurotrophic change in the nervous system which expressed itself not only in this form but in other similar conditions.

The PRESIDENT said that it was important to emphasize the fact that the encephalitis following vaccination did not occur in infancy, and that vaccination should be carried out as soon after birth as possible. It was important also that the child suffering from eruptions should not be vaccinated.

MATERNAL NUTRITION DURING WARTIME

At a meeting of the Medical Society of London on January 18, with Dr. HOPE GOSSE, the president, in the chair, a discussion took place on the subject of maternal nutrition, though it ranged also over the general subject of nutrition in wartime.

Prof. JAMES YOUNG said that from the evidence available it was not easy to determine the effect of the present planned dietary on the adequacy of maternal nutrition. The drastic restriction in meat, eggs, and fish had reduced the main sources of first-class protein and iron, and there had been a compensatory increase in the consumption of bread, potatoes, and other vegetables. Priority for milk for pregnant and nursing women had to some extent neutralized this dietary shift; priority in eggs appeared to be fictitious, and should not be taken into account in assessment of present nutrition standards. There was some evidence that deficiency anaemia was on the increase among women and infants, but none, so far as he knew, of calcium shortage. The incidence of rickets among infants required serious study. The intakes of vitamins A and D were relatively satisfactory because of the priority in milk and the fortification of margarine. The substitution of 85% extraction flour for white bread had improved the situation with regard to the B complex. There was some evidence of shortage in vitamin C.

He proceeded to give results of an investigation carried out by Dr. Hilda Hargreaves at the British Postgraduate Medical School on the mean birth weights of infants and the evidence of prematurity and immaturity during the years 1937-42 (omitting 1939). Prematurity was defined as birth before the 40th week, and immaturity related to infants under 5½ lb. in weight. The investigation had been restricted to booked cases only, and did not include cases admitted as emergencies. Comparing 1938 (the last full peace year) and 1942, the results were as shown in the accompanying table. Both in primigravidae and multigravidae there had been an appreciable fall in the mean birth weight of the infants. In the primigravidae there had been a striking fall in the prematurity rate during the years 1941 and 1942 (from 18 or 19% in the earlier years to 11.06% in 1941 and 12.18% in 1942). There had been no appreciable trend in the immaturity rate in either category. There had been a marked drop in the prematurity rate for primigravidae, but no similar decline in the immaturity rate, and the reason for this discrepancy was not easy to explain. It might be that, although in the earlier years the prematurity rate was higher, the drop in the mean birth weights of full-term children had in later years implied the transfer of a relatively larger number of infants during those years to the immaturity group.

Year	Total Births	Mean Birth Weight Full-time Infants		Premature Infants		Immature Infants (under 5½ lb.)	
		Number	lb.	Number	Per cent.	Number	Per cent
			Primigravidae				
1938	890	705	7·31	162	18·20	70	7 86
1942	804	679	7·08	98	12·18	73	9·07
			Multigravidae				
1938	875	740	7·54	108	12·34	48	5 48
1942	629	531	7 39	81	12·87	41	6 51

In conclusion Prof. Young said that a critical analysis of the evidence permitted some conclusions to be drawn, although many of the data were incomplete or equivocal. There could be no doubt that the dietary standards of the mother during pregnancy and lactation exerted a profound influence on her health and on the health and growth of the infant before and after birth. It had become clear that this was a dominating consideration in the social, economic, and administrative reforms directed to the improvement of the health of the nation

Broader Nutritional Considerations

Dr. T. IZOD BENNETT, after illustrating some of the results of vitamin deficiency, said that a great deal of nonsense had been and would be talked about vitamins. Instead of thinking in terms of normal human beings having more or less normal and varied food, many had approached this subject of vitamins from the point of view of laboratory animals placed on an unnatural diet and exemplifying gross deficiencies. The first law of nutrition was to ensure the primary elements of diet—protein, carbohydrates, and so on; and the second law was to ensure that these substances were given so far as possible in the form of natural food and not as synthetic preparations or extractives. If the latter expedient were adopted, and one factor, say a vitamin B complex, were added, there would almost certainly be a shortage of another factor which the chemist had not been clever enough to isolate; or, to put the matter more broadly, the primary constituents of diet were far more important than vitamins. If the natural foods were cut too low there would quickly be a shortage of some of the amino acids, which, although they might not be required in great quantity, were essential for the proper building up of protoplasm.

Some conditions which were described as due to vitamin deficiency were really due to psychological conditions or to faulty food habits; but these cases were very few and far between. Deficiencies were also seen in patients with ulcerative colitis, for example, due to excessive elimination. An increase in tuberculosis was sometimes ascribed to vitamin want, but he felt that it ought not to be so ascribed when such obvious causes as lack of ventilation and overcrowding might be cited. Neither in the wards nor in the out-patient department had he seen an increased number of deficiency cases.

Mr. ALECK BOURNE said that he thought it was the general experience that prematurity, which accounted for about 60% of all neonatal deaths, was very much conditioned by nutrition. He was surprised to hear that there was no vitamin deficiency at the present time in this country. This seemed contrary to the experience of Orr and others; there must, he thought, be a certain amount of subclinical deficiency. On the continent of Europe one of the most urgent tasks after the armistice would be the feeding of pregnant women. He believed that the rise and fall of tuberculosis depended to a considerable degree upon nutrition, and that an increased incidence was not to be put down solely to conditions arising from the black-out.

Correspondence

A Member Resigns

SIR,—Your leading article (Jan. 30, p. 135) is interesting; the member has done a service to the B.M.A. Your article shows the Association is perturbed by the letter and recognizes there is some reason for the member's criticisms. "There is no smoke without fire." I have been a member of the B.M.A. for over forty years and have seen many ups and downs, mostly "ups," as the B.M.A. has done great service for its members. We are now going through one of the "downs." Many members are threatening resignation, especially the younger ones; the older members are apathetic. I often hear them say, "What is the Association doing for its members?" Others say, "Only playing into the hand of the Ministry." I try to point out that members are answerable for the policy of its officers. "Why don't you attend meetings?" I ask. "What is the good?" is the answer; "too many old men in power and we are too soft to turn them out." The younger generation should now take its place on the councils of the B.M.A. The profession is hoping for a real lead by the B.M.A. in the future: not a bolstering up of the old methods, but a true progressive policy which will appeal to the younger generation. The Association is the largest and most powerful medical organization, but it appears to many members to show little originality in its policy.—I am, etc.,

Birmingham F. A. L. BURGES.

SIR,—I write as a member of twenty years' standing who has no intention of resigning his membership, in spite of not always seeing "eye to eye" with B.M.A. policy.

A patient, a member of the teaching profession, surprised me one day by saying, "Your profession has the strongest 'trade union' in the country." Thinking he meant the B.M.A. I disagreed with him, as in my experience negotiations between the Health Ministry and the B.M.A. invariably turn to the advantage of the former. He was thinking, however, of the power of the G.M.C., which is an entirely different matter, as I explained to him. This confusion of thought as regards the B.M.A. and the G.M.C. is not uncommon among the lay public, and something could be done to re-educate them accordingly.

The old saying that "the people get the Government they deserve" applies equally well to the British Medical Association.—I am, etc.,

East Kilbride JOHN MCLAREN, M.B.

SIR,—Your leading article published under the above heading (Jan. 30, p. 135) is interesting to me, a member of the B.M.A. for forty years. I am grateful for what they have done for me personally, on more than one occasion, as well as for the profession as a whole, both in and out of Parliament. The Association always takes a leading and honourable part in current medical topics. It always tenders sound advice when consulted by its members: Non-members are invariably welcome at its meetings. There is no other body of medical men more representative of the profession, both young and old, than the B.M.A. "Splitting," if there be any, is done by individuals, not by the Association. Medical progress cannot but be retarded by destructive criticism. But the respect of the general public is assured, as it is well aware of the power for good for which the B.M.A. stands and has always stood.—I am, etc.,

London, W 2 R. GALWAY MURRAY.

SIR,—As we have many organs in one body and all organs have not the same function, so we being many—general practitioners, consultants, surgeons, pathologists, and so on—are one body in the British Medical Association, whose organization corresponds to the nervous system which enables the body to act as a co-ordinated whole. That is the ideal. Alas, how far short of it we have fallen in the actual!

Perhaps the most serious result of this poor performance is that owing to failure on the part of members to make proper use of the Divisional Meeting the Central Executive is not brought under the will of the membership. Now to justify its existence an executive must act in obedience to the will either of those who have placed it where it is or of some other interest, whichever applies the greater pressure. Every self-respecting executive would prefer to obey the former, but it cannot choose. It must ultimately yield to superior force, wherever it comes from, or resign. The Executive of the B.M.A. is no exception to this law. We, the members, have failed to give it a proper backing, and now there is lots of evidence to prove that it has been yielding to outside pressure. Neither the members nor their patients have ever demanded a planned medical service, except as moved by propaganda, and yet our Executive is actively engaged in the furtherance of such a scheme. It justifies its action by declaring that its plan is designed to save us and the country from the imposition of a somewhat different plan of which it does not approve. But this is merely to confess that the B.M.A. has lost the initiative and that it is no longer master in its own house. Were space available particulars might be given of the nature of the outside pressure which is being applied, but, since it is not, these details, which are of relative unimportance to the present argument, must be omitted.

From what has been said it now appears obvious that the essential task of the moment is to achieve unity within "the body," and to take the necessary steps to generate a sufficiency of force to eject the invader. That boils down to improving the mechanism by which the member may impress his will on the Executive, and inducing him to use it. Brief references will now be made to three portions of this mechanism.

(1) Annual Representative Meeting. This appears useless for the purpose mentioned. If the report in the *Supplement* of the last A.R.M. was a true picture then the meeting was a fiasco. Something must be done about it. I don't quite know what.

(2) Our Representatives. These must take their job much more seriously than is usually the case. They must find out what their constituents want and continuously press these demands on Headquarters, not wait for the A.R.M. Perhaps some paid representatives would be worth while.

(3) Divisional meeting (political). Everything depends on this. It is the power house. It is the source of policy. It represents the circumference from which a continuous stream of stimuli should pass to the centre, keeping it up to scratch. Here are the end-organs keeping the mind in touch with reality. Members should state clearly what they want in both particular and general terms, and transmit these demands through their representative to Headquarters. The following is an example of a general statement of policy presented to one Divisional meeting for its consideration: We want, before every other professional consideration, freedom to function as doctors in response to the demands of our patients and to the satisfaction of the persons immediately concerned. Any interference with or threat to this freedom shall be resisted with all our power.

I have a good deal of sympathy with the writer of the letter which is the subject of your leader, "A Member Resigns." He sensed truly that there is something seriously wrong. He acted. Unfortunately, in my opinion, he acted ill-advisedly. I hope he will reconsider his decision, and that if at some future date he should desire to rejoin the Association no difficulty will be placed in his way.—I am, etc.,

Bexley, Kent. E. U. MACWILLIAM.

"Calorie Control" Diabetic Diet

SIR,—Dr. A. C. Crooke's article (Jan. 16, p. 64) appeared to suggest the practicability of permitting a free interchange of carbohydrates, proteins, and fats in diabetic diets, providing the total caloric value remained constant. Dr. R. D. Lawrence (Jan. 30, p. 143) queried, I think with justification, both the theory and practice. Dr. Crooke then made it clear that he meant "within the limits of experiments described." Perhaps these limits could be defined more clearly and mathematically, in respect not only to permissibility but also to actuality. As regards theory, Dr. Crooke draws attention to Prof. Ellis's experiments in which he replaced proteins and fat by their glucose equivalent, and found, as a result, a strikingly diminished insulin requirement. I wonder if these important experiments are strictly applicable, since (1) Ellis did not suggest that there was no need to vary the insulin dosage accordingly—on the contrary very rapid changes were necessary; and (2) he gave the insulin and glucose hourly throughout the day and night.

Nevertheless, it is true that when Pörges and Adlersberg first suggested high carbohydrate diets in diabetes there were objections raised on physiological grounds. It may be that further clinical experiments will justify Crooke's suggested innovation, but until then I think it more prudent for those in charge of diabetic patients to adhere to present practice.—I am, etc.,

London, W.1. S. L. SIMPSON.

SIR,—Dr. A. C. Crooke (Jan. 16, p. 64) proposes an interesting revolution in diabetic dietary, and claims that he has shown this revolution to be successful in a number of cases. In fact he has shown no such thing. He claims that protein, fat, and carbohydrate are interchangeable in a diabetic diet so long as the calorie intake is constant. This is a remarkable claim, and it is made without evidence, for he gives no details of the actual carbohydrate, protein, and fat intakes of his patients. Dietary habits are hard to alter, and it is most likely that the majority of his patients retained their previous diets more or less intact. Who would choose to have nothing but bacon and butter for breakfast if cereal and bread are available? Further, wartime restrictions (even with the extra allowances for diabetics) make it impossible to subsist entirely on protein and fat. The diabetic ration allows about 75 g. protein and 100 g. fat. This gives 1,200 calories, so that 200 g. carbohydrate are necessary to make up a diet of 2,000 calories. This is a reasonable orthodox diet and may well have been the diet taken by Dr. Crooke's patients, who were allowed 2,000 calories.

To substantiate Dr. Crooke's claim it would be necessary to study in-patients (who alone can be brought under accurate dietary control), to balance them with insulin on pure carbohydrate diets, and to estimate their blood sugar throughout the day. Then they would have to be put on to pure protein and fat diets of the same calorie value with the same insulin dosage. If his hypothesis is correct then the blood-sugar levels throughout the day should remain unchanged. Until such evidence is forthcoming it would be foolish to accept Dr. Crooke's revolutionary hypothesis. In peacetime, with unlimited protein and fat, it might be dangerous. There is, however, one inference that may be derived from his paper, and that is, that diabetics are very conservative in their dietary habits. It is important to remember this when conclusions are reached as the result of experiments with out-patients.—I am, etc.,

St. Bartholomew's Hospital, E.C.1 C. M. FLETCHER.

Nomenclature of Typhus Group

SIR,—In your issue of Nov. 21 (p. 597) Dr. A. Felix, in discussing the nomenclature of the typhus group of fevers, takes me to task for the alleged recent introduction of the term "exanthematic" typhus as a synonym for louse-borne typhus. The propriety of using the adjective "exanthematic" in speaking of the relationship between louse-borne and flea-borne typhus, in which latter condition the rash is as a rule less in evidence than in louse-borne typhus, may be open to question. It is, however, incorrect to assert that "exanthematic" as applied to typhus is "a new invention." Dr. Felix can hardly have forgotten that on the Continent "typhus exanthematicus," "typhus exanthématique," and "tifus exantemático" have been in use for many a long day. An examination of past volumes of the *Tropical Diseases Bulletin* and of standard English textbooks here available, many of them by no means recent, shows that the term "exanthematic" applied to louse-borne typhus is of such an age that I cannot well claim its parentage even if I had wished to do so.—I am, etc.,

G. M. FINDLAY.

Eventration of the Diaphragm

SIR,—I venture to think that Dr. Mills (Jan. 23, p. 97) is incorrect in regarding his interesting case of eventration as congenital in origin. The clinical and radiological features are rather more in keeping with a diagnosis of *aérogastrie bloquée*, which he dismisses, I think, too lightly. I am not familiar with the occurrence of the cup-and-spill or cascade type of stomach in congenital eventration of the diaphragm, but it has been a feature of all of the four or five cases of *aérogastrie bloquée* that I have seen. The loculation is due to the pressure of gas in the splenic flexure of the colon and has been well called the pressure hour-glass effect. It is my belief that the condition of *aérogastrie bloquée* starts in an upper gastric loculus formed in this way. In this loculus gas is trapped, and as its pressure increases the cardia becomes displaced and relief by belching is prevented. Two of my patients could not belch wind and never had been able to as long as they could remember. The upper loculus gradually distends backwards and upwards, pushing the left dome of the diaphragm into the thorax and the heart over to the right. Pain, and sometimes very severe pain, is a common though not invariable symptom; fullness and distension are usual, and sometimes an upper abdominal tumour may be visible. In my view, then, Dr. Mills's case is one of eventration of the diaphragm secondary to *aérogastrie bloquée*.

I was not aware of Korns's sign, but the divergence of the costal margin on inspiration is an interesting and somewhat neglected physical sign in diagnosis, occurring to a greater or less extent in all cases where contraction of the diaphragm is exerted through an arc greater than normal, thus offering less than its usual antagonism to the intercostal muscles. The movements of the costal margin as an aid to diagnosis are well described by Charles F. Hoover in the Nelson *Loose Leaf Medicine*, Volume III.—I am, etc.,

Birmingham. T. L. HARDY.

Houses to Live In

SIR,—"Homes to Live In" would have been even better for the title of your leading article (Jan. 30, p. 136). You will say that that was not the question asked, but I reply that it ought to have been. We are all out for that "harmony of human relationship" mentioned in the review of *Psychological Effects of War on Citizen and Soldier* (Jan. 30, p. 133), and here is a great opportunity for our profession not to accept calmly the *status quo* or to stand by while grievous wrong may be done to the body politic. Every person is entitled in a democracy to be recognized as a personality, the roots of which are embedded in family life. We may play a large part in insisting upon this. The College should emphasize the fact that tenement flats are destructive of family life. The sound instinct and knowledge of the people recognize this, and over 90% of them have said so. Warehousing our peoples does not make for a vigorous people full of initiative.

You may wonder why I say this, but it is not possible to argue this question without the knowledge that vested interests in the land of great cities and in the materials of which flats are made are looking for encouragement just now, and it should be our business not to appear as "appeasers." Harmony of social life demands a positive policy. We do not want to wake up to find that damage has been inflicted upon people by foisting on them a sterile unimaginative static condition which need not exist.—I am, etc.,

Letchworth, Herts NORMAN MACFADYEN.

Sulphonamide-resistant Bacteria

SIR,—I was much interested in the article by J. Petro (*Lancet*, 1943, 1, 35) on the increasing incidence of a strain of gonococcus which is resistant to the action of the sulphonamides. I think a fair inference is that this strain has become resistant due to the ineffectual treatment of patients by too small doses of the sulphonamides. Is it not time that the medical profession at large realized this danger, and took greater care to avoid breeding strains of organisms which may spread, and thus give rise to a state of affairs approximating to the pre-sulphonamide era?

I have in mind particularly the treatment of streptococcal sore throats by means of these drugs. It was, and to some extent still is, the practice of many nurses, medical students, and even medical men to take a sulphonamide whenever they have a sore throat. The doses are nearly always much too small, so as to avoid the unpleasant side-reactions. Even with the very best use of these drugs, it is practically impossible to remove all haemolytic streptococci from an infected throat, and those which remain are resistant to further dosage. If this germ is now coughed on to the perineum of a puerperal woman she is likely to have puerperal sepsis of the resistant type. Only a day or two ago I came across a case of a medical student, now engaged on her "midder" course, who had a sore throat and was taking large doses of sulphapyridine even before the bacteriological diagnosis was completed. Presumably, she would have been excluded from the midwifery wards until her throat was pronounced clear of haemolytic streptococci after three swabs; but this precaution is by no means universal, and many a doctor must return to his practice still carrying haemolytic streptococci in his throat, now with an increased fastness to these drugs. Before the sulphonamides sore throats were very successfully treated by the medical methods of gargles, etc. I feel strongly that we should return to these methods of treatment, and only use these new drugs when we are sure that we can completely exterminate the germ population which is the cause of the disease we are treating, or when no other treatment will succeed.—I am, etc.,

Amersham HENDRIK MULLER.

Military Psychiatry

SIR,—The last paragraph of Dr. Richard Eager's letter (Jan. 23, p. 111) suggests that insufficient attention is being given by medical recruiting boards to nervous and mental manifestations before enlistment. It is not so easy as that. A psychoneurotic can appear before a board and be found physically fit and answer all questions intelligently without disclosing previous neurotic attacks. And, in point of fact, he may be truthful, for in the even course of civil life no abnormal mental condition may ever have been evoked. Medical boards are not slow to consult their psychiatrists if there is any indication of mental deficiency. Modern Army "toughening" conditions find various recruits unable to respond to the demands made upon them, and an anxiety neurosis develops which goes from bad to worse in their course of intensive training.

The remedy does not lie in making recriminations to the boards and discharging these cases from the Service, but in further efforts to secure proper adjustment. Many a man found unsuitable for a machine-gun team would be quite all right as a batman or in equipment stores or the cook-house. The number of discharges is far too large. Few regimental medical officers, however, can spare time to supervise a neurotic, especially one who is keen to get out of the Army and finds a claim to nocturnal enuresis or other malingering devices an ever-present help in regaining his freedom from service.—I am, etc.,

Dalkeith, Midlothian G. DOUGLAS GRAY.

Unwarranted Cardiac Invalidism in Children

SIR,—With reference to Dr. R. P. Garrow's letter (Jan. 23, p. 114) may I report a case which is very illustrative of the risk of undue stress being laid upon systolic murmurs without more detailed examination by radiology and, where possible, the electrocardiograph.

In 1930 I was asked, incidentally to a private visit, to examine a younger sister of a friend. With the stethoscope there were gross murmurs, which I have since loosely described as "the thorax was like a musical box." I found the child had always been healthy, but this condition had been discovered by routine school examination. The mother had been told to take the child to one of the large teaching hospitals, I think, every fortnight. I refused to give an opinion until the child had been brought to me for x-ray examination, when I found the heart normal in position, contour, size, and pulsation. I then took upon myself the responsibility of telling the mother not to take her again to the teaching hospital, as this could only be for demonstration purposes, and in my opinion would render the child a pampered chronic invalid. Meanwhile I advised moderation in exercise and that the child should certainly attend school. I re-examined her three months later and I have seen her from time to time. Later the child not only excelled in all sports, particularly high-diving, but had a brilliant scholastic career, gaining the B.Sc. and higher qualifications, with appointment as a demonstrator at a university. A pretty girl, a brilliant academic career appeared likely when, last July, she came and informed me she wished to forgo this future to join the W.R.N.S. without any compulsion to do so, but was afraid she would be rejected, and asked my assistance. I wrote a letter stating her case to the relative medical board. On stethoscopic findings the board was apparently afraid to pass her but sent her to a well-known cardiologist. He concurred in my opinion, she was passed, and now for many months has been engaged, I understand, on mathematical calculation work of a metrological nature.

I feel sure that had earlier importance been placed upon this very marked case of systolic murmurs, with years of attendance at hospital for demonstration, the child would have long ago been a chronic invalid. In numerous cases of heavy life policies, after disclosing the facts of systolic murmurs with radiological normality I have recommended first-class acceptance, and, to date, have never been informed by the respective insurance companies that my recommendation has resulted in early decease and payment of the insurance.—I am, etc.,

London, E.7 BERNARD LEGGETT.

Ethyl Chloride Spray in Pleuritic Pain

SIR,—In view of the relief afforded to patients with sprains of the ankle and similar conditions by spraying the part locally with ethyl chloride, it occurred to me to try the method in cases of pleuritic pain. The effect proved to be pronounced and immediate, and the relief experienced by the sufferers distinctly gratifying.

The method is simplicity itself, consisting in locating the pain so far as possible, which, generally speaking, is not difficult, and spraying a patch over it about 2 inches square with ethyl chloride till blanching occurs. Often a single application is enough, but in cases of very sharp and severe pain which is only mitigated and returns in a short time further applications may be made. I should think it is worth while to call—or maybe to recall—the attention of the profession to this extremely simple and apparently harmless method of relieving what is often a most distressing symptom.

I should be interested to hear of the effect in pneumonia and allied conditions, as my own experience is for the most part limited to pleuritic pain arising in connexion with tuberculous lesions. No doubt there are a number of other conditions amenable to this form of therapy. For instance, one patient recently, who had severe pain over the right frontal region due to sinusitis, experienced immediate relief. In this case it was, of course, necessary to shield the eye itself from the spray.—I am, etc.,

NORMAN MACDONALD.

Diphtheria during Immunization

SIR,—It would be a pity if such a case as is recorded by Dr. G. A. Garrett (Jan. 23, p. 102) were to be numbered under the above heading. The case is clearly one of follicular tonsillitis in one who was a carrier of the Klebs-Loeffler bacillus. There was no clinical diphtheria, which would have required both notification and antitoxin. There is no evidence that a prophylactic activates a dormant bacillus. The suggestion to swab all throats before inoculation and use antitoxin in cases with a positive finding is not a practical policy and would greatly interfere with prophylaxis. I had a nurse who was a carrier of K.L.B. who had to leave hospital and was in an infectious diseases hospital for three months to clear her throat, but it was found impossible to do so. Carriers are not all easily cleared of their variety of K.L.B. The diagnosis of diphtheria rests on clinical phenomena and not on the presence or absence on the swabs of K.L.B.—I am, etc.,

Southsea A. G. NEWELL.

Oestrogen Treatment of Diabetes

SIR,—I was very interested in the annotation on the oestrogen treatment of diabetes (Jan. 23, p. 107). It may interest you to note that I have observed in several cases the beneficial effects of the male hormone in reducing glycosuria and elevation of the blood sugar. One's observations on the male hormone in relation to this particular problem bear out what one has so often observed in other circumstances—i.e., that the male hormone is less an antagonist of the female than an equivalent and sometimes a dominant. Expressed otherwise, in some conditions—e.g., post-involutional depressions in women—where you get a good result with the oestrogens, you can often anticipate an even better result if you switch over to testosterone. I have observed the beneficial effect of testosterone in other conditions—e.g., thyrotoxic states.

I am convinced that the future will reveal a far more ubiquitous usefulness for sex hormones, particularly the male. I feel that one is a little too diffident in experimenting with these problems in widely differing conditions. One feels illogically that one is utilizing something like a "cure-all." I think we shall find that the sex-gland products are among the most ubiquitously useful of all therapeutic agents, and that inability to recognize this fact is responsible for a great deal of retardation in the development of therapeutics. For instance, despite the fact that it is established that in certain cases of hyperpiesis the hormones, the oestrogens in particular, will reduce blood pressure with the most beneficial effects where nothing else will, I encounter such cases, not by any means frequently, but steadily and persistently, and it surprises me greatly that such methods are not more widely used.—I am, etc.,

Bath A. GUIRDHAM.

Thrombophlebitis of the Cavernous Sinus

SIR,—Dr. A. R. C. Doorly, in his interesting account of a case of thrombophlebitis of the cavernous sinus (Jan. 9, p. 42), discusses the surgical treatment of the established condition and of the local lesion, concluding that the safest course is the combination of sulphathiazole therapy with repeated transfusions. There remains one simple surgical measure of very considerable value in the prophylaxis of cavernous sinus involvement which he does not mention, although its timely employment may entirely avert that grave complication. I refer to ligature and division of the angular vein, whose tributaries include the small veins of the ala nasi. Mr. Hamilton Bailey, discussing the indications for this operation (*Emergency Surgery*, 4th edition, p. 559), says: "... the necessity for timely interference must always be before us. On the whole it is better to err on the side of activity. A sign which foretells impending danger is oedema spreading from the lip to the inner canthus, and this is usually found in the presence of suffusion of the eyelids. As far as my own observations have gone, the premonition is invariably unilateral. If in addition to this sign there is considerable elevation of temperature, the call for action is imperative."

It is, of course, impossible to determine whether in the case described ligature and division of the left angular vein on the second or third day would in fact have prevented cavernous sinus thrombophlebitis, but this operation deserves a place in any consideration of the treatment of pyogenic facial infections in the danger area.—I am, etc.,

D. STAFFORD-CLARK.

Measles associated with Unusual Nervous Signs

SIR,—The following report of a case of measles associated with unusual nervous signs may be of interest.

The patient, a girl of 4, was seen six hours after the appearance of the rash. She was tossing violently about in bed. Examination revealed this to be due to vigorous pronation–supination movements of the limbs on the left side. The head was rapidly following the direction of these movements. The child was semi-conscious, and there was urinary and faecal incontinence. The mother stated that these signs all came on suddenly about an hour before my arrival. A history of repeated attacks of vomiting since the previous day was obtained, but nothing abnormal was discovered on abdominal examination.

The temperature was 101° F., pulse rate 112, and respirations 32. The rash was typically morbilliform in appearance and distribution, and was accompanied by the usual catarrhal signs. There was no neck rigidity, nor could Kernig's sign be elicited. Tendon jerks on the affected side could not be estimated due to the violent muscular movements, and were absent on the opposite side. There was a weak extensor plantar response on the affected side, and a normal flexor response on the other. Both pupils were dilated and equal and sluggishly reactive to light. The cutaneous abdominal reflexes were present and brisk. The cheek muscles on the affected side were markedly less prominent than those on the other, but there was no facial paralysis. The mother stated that the discrepancy in the size of the cheeks had been present from birth. The confinement had been normal, no instruments were used, but the child had had "violent muscular twitchings" for four days after delivery. These had then subsided, and the child made normal progress, although it was "slightly backward in its speech" and "very perverse by nature." There was no history of any previous infectious disease, or of injury of any sort. The child was put on a mixture of sod. salicyl., tinct. camph. co., and pot. brom.

The next day (second day of the disease) the patient was much better generally. The muscular over-activity had completely subsided, but there was flaccid paralysis of the limbs on the affected side. The tendon reflexes could not be elicited on either side, but there was a very marked extensor plantar response on the affected side. The opposite plantar response was normal. The pupils were still dilated, but reaction to light was good. Vomiting had ceased, also incontinence. The temperature and pulse were similar to the previous day, but the respirations were down to 24 per minute.

On the third day the general improvement was maintained. The temperature was 99° F., pulse 92, respirations 20. The tendon jerks were present, but weak on both sides. The plantar extensor response was vigorous on the affected side. The limbs on this side were markedly improved. The child was able to raise its arm through an angle of 60 degrees, and could hold a small article (i.e., coin) in its fingers, which it could not do on the previous day. It could also slightly raise its leg. On the fourth day the child appeared a normal fourth-day measles, the only remaining abnormal C.N.S. sign being a Babinski on the left side, and this was much less vigorous than previously. Complete range of movement had returned to the left arm and leg. On the fifth day the Babinski was replaced by a flexor response, and from then onwards the child progressed normally, all abnormal C.N.S. manifestations having completely disappeared.

Osler states that out of 120 cases of measles complicated by hemiplegia, only four developed the nervous signs during the course of the fever, and the condition usually persisted. In this case all abnormal signs had disappeared by the fifth day.—I am, etc.,

Leicester. C. M. WARNOCK.

Prevention of Sterility

SIR,—Dr. E. Schleyer's three comments on the prevention of sterility (Jan. 16, p. 71) are timely, but I do feel that he has merely touched on the fringe of this important subject. All medical men are aware of the scientific reasons for sterility and the appropriate treatment, but very little attention has been paid to the non-scientific but nevertheless important group of apparently sterile marriages.

1. The couple who are over-anxious to have a child adopt excessive coitus, which results in complete saturation of the vagina with seminal fluid and vaginal secretions, which trickle out of the vagina. Secondly, excessive copulation has an adverse effect on the nerves of the man and woman, which soon leads to disharmony and marital quarrels. This affects the wife deeply, and she, unhappily, dislikes the mating. This method can result in conception, but to both partners it is a nerve-wracking business and not a pleasure. Treatment is based on an explanation on the lines of the above, and separation of the couple for a time: if this is not practicable, avoidance of coitus for a time.

2. The couple who for financial reasons or even selfish reasons adopt methods of contraception and then at a later date decide to have a child. The flora of the vagina and even the normal secretion have become changed by contraceptives or by chemical douching after the act. These substances and/or the changed flora militate against the normal activity of the spermatozoa. (This does not occur with the sheath or Dutch cap.) Treatment: Douching with plain warm water; an active outdoor life; good wholesome food with an adequate amount of fat.

3. The woman who as a result of hypersensitivity and/or sensuality has a firm and prolonged "vaginismus" which at the climax expresses the seminal fluid. Treatment: Avoidance of parties, cocktail or otherwise; in other words, a quiet, ordered life; bromides; instruction of the husband how to promote an early climax in his wife so that his orgasm occurs after hers.

Having decided the cause of the apparent sterility, there are five further considerations for the family doctor. (*a*) Age—A woman in her forties may be passionately devoted to children in the abstract, but when confronted with a yelling infant of her own who requires constant attention now finds herself tied down and not able to be a companion to her husband, who finds it more comfortable to be out. Of course the maternal and infant risk is great. (*b*) Past and present health of the mother to be—albuminuria of pregnancy, for example. (*c*) The pelvic measurements—It would be very unpleasant to inform the mother that the created baby can only be delivered by Caesarean section (to a layman this is a major catastrophe). (*d*) A family history of tuberculosis, mental disease, etc. (*e*) Financial.

Lastly, I have been faced with the problem of the wife who desires a baby before her husband goes abroad. The method I have adopted is purely mechanical, and the advice given has been successful in nine cases out of eleven apparently sterile marriages. Five young couples had been married only a short time; two cases had been married five years, one six years, and one eight years. The method adopted is as follows. The woman places one or two pillows beneath her buttocks and coitus takes place. This allows deeper penetration and seminal fluid is thrown deep into the vagina and even over the os. The woman remains in this position for the rest of the night. The most fertile time is believed to be two weeks before the period and after, or at such time when the woman is "desirous of coitus." The above idea I think is not entirely original.—I am, etc.,

Boston, Lincs G. R. DARLEY-USMAR.

Dietetics of Pregnancy

SIR,—Mr. R. B. Fisher (Jan. 30, p. 144) is mainly critical of the results of certain field experiments. Among other statements is the following: "The work of the People's League of Health has been dealt with ably and forcibly by Doyne Bell in a discussion at the R.S.M. and has been reported on in your columns. I would refer your readers to the full report in the current issue of the *Proceedings of the Royal Society of Medicine.*"

The statement made by Dr. Doyne Bell which related to the investigation by the P.L.H. was as follows:

> "A research also addressed to the problem of the effect of diet upon the infant was initiated before the war by the People's League of Health, and an interim report has been published in the *B.M.J.* and the *Lancet*. Unfortunately the concept of prematurity, defined as birth before the 40th week of gestation, has been used as a yardstick to measure the success of the changed diet. In order to try to assess the suitability of such a yardstick for this purpose, I have, with the permission of Mr. Eardley Holland, taken a random series of 147 babies born in the London Hospital in 1938 and 135 babies born in 1942 and have made a histogram of their estimated gestation periods. . . . It will be seen that in 1938 the estimated gestation periods are distributed normally about the 40th week with a standard deviation of approximately ±10 days—that is, between 3 and 4%.
>
> "This observation leads to the expectation that one-eighth of all normal gestations will terminate before the 40th week. I venture to suggest that the differences of 3.8±1.10% for primigravidae and 4.1±1.33% for the multiparae achieved by the dietetic methods adopted in the work sponsored by the People's League of Health are probably of no significance. My conclusion is reinforced by their admitted failure to influence the birth weight of the babies."

As we were the statisticians who carried out this particular analysis we think it proper that we should give an answer to the criticism passed on this work. We think that Dr. Doyne Bell's knowledge of statistical technique is somewhat imperfect, because we have never even claimed the degree of statistical significance in our results which he ascribed to them. For example, the difference in the incidence of prematurity between treated and controls, primiparae, was 3.8%, and it had a standard error due to sampling of the magnitude of ±1.58, not ±1.10 as stated by him. He has erroneously regarded the standard error of a percentage as identical with the standard error of a *difference* between two percentages.

We admit that a significant increment in prematurity was unaccompanied by a significant decline in the mean birth weights, but there is nothing contradictory in this result. A difference of 3.8% between the respective primiparae groups represents an excess of 54 premature births, and it is unlikely that this number would influence significantly the mean birth weight of the control series based on 1,512 observations (especially as all premature babies are not subnormal in weight).

As regards Dr. Doyne Bell's own data for the London Hospital, he states that in the statistics for 1938 "the estimated gestation periods are distributed normally about the 40th week." This statement is not correct, because, in point of fact, 22% of the observations were under 40 weeks and 54% over 40 weeks. It would be interesting to discover the statistical basis for his statement that "one-eighth of all normal gestations will occur before the 40th week." What is meant by normal in this instance? If it were a normal distribution, then 50% of the observations would occur before the mean value of 40 weeks. But the actual distribution recorded by him does not follow the normal curve; it is not even symmetrical. We maintain that there is no justification for his particular statements.—We are, etc.,

Obituary

SIR STCLAIR THOMSON

Dr. DOUGLAS GUTHRIE writes: It is hard to realize that Sir StClair Thomson has left us. His genial presence, his unaffected simplicity, his wide grasp of affairs, and his many interests made him a delightful friend whom it was always a real pleasure to meet. Those of us, and many we are, who accepted his kindly hospitality in Wimpole Street can never forget him as the perfect host who loved to converse with his guests in his own inimitable fashion, or to show them, with pardonable pride, some of the treasures of his charming home. Young specialists from the Provinces, distinguished foreigners, and London colleagues were all equally welcome, for he was the first to entertain the stranger when any meeting relating to laryngology was held in London. Since coming to Scotland two years ago he had renewed old friendships and had made many new acquaintances, as was natural to one so approachable and so friendly. Before settling in Edinburgh he spent some months in his native county of Argyllshire, but, as he remarked to me, he found it "too quiet for a young fellow like me." Despite his 80-odd years his heart was ever young and he loved the society of youth. An invitation to address the Students' Medical Society of Edinburgh University gave him the keenest satisfaction, his pleasure being shared by all who were privileged to hear his sparkling description of "A House-surgeon's Memories of Lister." It was characteristic of Sir StClair Thomson that one of his last acts was to visit in a sanatorium near Edinburgh a medical man suffering from tuberculosis of the larynx. "Not that I can do much for him," he remarked, "but I can at least tell him of my own experience, and that always cheers a patient up." Sir StClair Thomson was the embodiment of cheerfulness; and what sweeter memory could he leave with us, his friends and colleagues?

Dr. ALFRED COX writes: The tributes to Sir StClair Thomson in the *Journal* are a graceful and fitting memorial to a great doctor, but I miss any reference to his particular services to our Association, which were many. I do not allude to his official connexions with our Annual Meetings, but to those services which are unrecorded. When I was Medical Secretary I often had to appeal to him for help and never in vain. Once, when the Section of Laryngology seemed likely to be a failure owing to certain personal difficulties, he intervened at my request at the last moment and succeeded in steering us round a very awkward corner. Nobody but he could have done it. And those who were present at the Annual Meeting Dinner at Winnipeg could never forget the way in which he intervened at a critical moment when disaster seemed to be imminent. The room was very crowded; some of those at the back had difficulty in seeing and hearing; there had been two very long and rather dreary speeches; and the younger and more remote sections of the dinner party began to be decidedly restive. The President changed the order of the toast, called on Sir StClair Thomson, and in two sentences he had the whole company cheering and laughing. I have heard of similar instances, but this one remains deeply impressed on my mind. Tact and a supreme gift for diplomacy and friendliness were among his great gifts. I doubt whether there was any man in our profession in his time more deservedly popular and loved than he was.

ROBERT HENRY PARRY, F.R.C.S.ED.

The death of Mr. Robert Henry Parry, which occurred in London on January 22, will stir feelings of regret in many who recall their memories of the Glasgow School in the period 1890–1920. Not favoured by early fortune, he overcame by ability and by hard and sincere work many difficulties, and reached an established and recognized position as a surgeon and teacher in Glasgow and the West of Scotland. In one respect he was granted a special opportunity, for he lived in the day when a new hospital was built—the Victoria Infirmary, Glasgow—and he was appointed by a courageous board of directors as surgeon in independent charge of wards at a comparatively early age. By the quality of his work he promptly justified this appointment, and soon, developing his natural teaching ability, he attracted many students both to his clinic and to his class-room. From this developed naturally a rapidly growing consulting practice, while by his manifest sincerity and readiness to co-operate Parry was always on excellent terms with his colleagues. He cultivated a wide sympathy in the practice of surgery, and was a bold and skilful operator.

When he retired to the South of England in 1923 he had hoped to collect for publication a record of his accumulated experiences, and to cultivate laboratory research work. Unfortunately his health soon failed, and for several years before his death he was an almost helpless invalid. Hence his published contributions to surgery are relatively few in number, but in them may be recognized the thoroughness and enterprise well known to his contemporaries. It is mainly through his work at the Victoria Infirmary and at the Royal Hospital for Sick Children and through his pupils, whose devotion and gratitude to him never failed, that Parry made a valuable contribution to his day and generation. He became a member of the B.M.A. in 1888 and took an active part in the Annual Meeting at Glasgow in 1922. By his colleagues he was elected to many positions of responsibility and honour, and many of these will recall memories of his loyalty and good-fellowship. In his home and family life Parry found both help and solace, and to his widow and his two sons many friends will desire to offer an assurance of sympathy and regard.

C. O. H.

CHARLES JOHNSTON-SMITH, C.B.E., F.R.C.S.ED.

The death of Prof. Charles Johnston-Smith at the age of 62 in St. Mary's Hospital, London, on Jan. 25 will be a source of grief to many medical men who knew him in the Far East, where he occupied an eminent position in surgery for many years. Son of an Edinburgh schoolmaster, he was educated at the Royal High School, Edinburgh, and at Edinburgh University, where he graduated M.B., Ch.B. in 1904 and proceeded to the F.R.C.S. in 1909. After occupying various surgical posts in England he went to Malaya in 1911 and joined the Government medical service. At first he worked in the small town of Seremban, and had a splendid surgical clinic there. Later he moved to Singapore, where he was senior surgeon in the general hospital and professor of surgery at the Singapore School of Medicine. He was a most dexterous and courageous surgeon, and on more than one occasion successfully sutured a cardiac wound. He made many technical improvements in the operation of splenectomy. Johnston-Smith had a commanding and distinguished appearance, the embodiment of the popular idea of a surgeon. His kindliness to his patients and all around him, and especially to the newly arrived house-surgeon, made him a much-loved man. Although deafness was a great handicap it did not make him remote, and the picture of him with hand "capped" over his ear and kindly smile will long be remembered. Notwithstanding his long stay in the Tropics and his poor health he started in surgical practice in Guernsey in 1936, the year after he retired from Singapore, and was soon as popular on that island as he had been in Singapore. He was surgeon to the Victoria Hospital, Guernsey. His life was a long struggle against pulmonary tuberculosis, which eventually claimed him, after thirty years of battling against it. His ending was particularly sad, for his wife, Kathleen, to whom he was devoted, was a prisoner in Guernsey and his two daughters were far away when the end came.

Dr. **ORBY RUSSELL MORGAN WOOD**, who practised for many years at Woolpit, Suffolk, was the son of the Rev. Dr. Wood of Woodbridge and received his medical education at the University of Edinburgh, taking the Scottish triple qualification in 1889 and the M.B., C.M. degrees in 1890. Dr. Wood joined the B.M.A. in 1893, was a member of the Central Council from 1913 to 1918, and represented his constituency at five Annual Representative Meetings. He was vice-chairman and a member of the executive committee of the West Suffolk Division from 1914 to 1919 and represented his Division on the Suffolk Branch Council in 1920 and 1921. During the war of 1914-18 he served for three years as temporary honorary secretary of the Division. In 1921 he was elected president of the Suffolk Branch, becoming vice-president in the following year. After his retirement he was elected an associate member of the Branch in 1926.

Universities and Colleges

UNIVERSITY OF OXFORD

In a Congregation held on Jan. 21 the following medical degrees were conferred:

B.M., B.CH.—R. C. Evans, A. M. N. Gardner, J. K. Hawkey, A. M. Sweet, A. W. F. Erskine, D. C. Byron-Moore, G. M. T. Tate, F. E. Lodge, Margaret Myers, Renate H. Schulz, *D. F. Barrowcliff, *B. Bevan, *W. B. Matthews, *L. P. Le Quesne, *A. I. Spriggs, *E. L. Barr, *C. S. Gardner, *R. T. C. Pratt, *D. M. Strathie, *P. Vlasto, *D. J. Arkle, *Constance L. Simpson.

* In absence.

UNIVERSITY OF CAMBRIDGE

The titles of the degrees of M.B., B.Chir. have been conferred by diploma on H. M. Comely of Girton College and P. B. Shaw and Mrs. M. E. Wehner of Newnham, and that of M.B. on Mrs. P. M. Dobbs of Newnham.

UNIVERSITY OF LONDON

The University College Hospital Medical School announces that two Goldsmid Entrance Scholarships, entitling the holder to the final course of medical study, will be offered for competition in July. They are open to students who are preparing for the degrees of the Universities of London, Oxford, Cambridge, Durham, or other British universities, or for the diplomas of the Royal Colleges of Physicians and Surgeons; also one Goldsmid Entrance Exhibition and one Filliter Entrance Scholarship in Pathology entitling holders to a reduction by £80 and £52 10s. respectively of the fees due for the full course of final medical study. Notice of intention to compete must reach the secretary of the school (from whom full particulars can be obtained), University Street, Gower Street, W.C.1, by July 3.

ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS

A quarterly meeting of the Council was held on Jan. 30, with the President, Sir William Fletcher Shaw, in the chair.

The following were admitted: *To the Membership:* Janet E. Bottomley, Phillis Dingle, Marjorie O. Dunster, Christina McD. McTaggart, L. Resnick, G. S. Sturtridge, K. G. P. Worner.

CONJOINT BOARD IN SCOTLAND

The following candidates, having passed the final examinations, have been granted the diploma of L.R.C.P.Ed., L.R.C.S.Ed., L.R.F.P.&S. Glas.:

M. W. Awad, J. D. H. Bankier, Margaret Barker, J. S. Bateman, C. E. Bell, J. M. Bolton, J. N. G. Burns, D. S. H. Cadzen, N. A. Chisholm, R. P. Cookson, J. H. Couper, Margaret M. A. Dunn, O. Ellabewitz, Margaret S. Elliot, G. St J. Frost, M. Gaines, S. J. Halkett, I. Hamilton, Isobel M. Hill, Regina Kemmerling, A. Manson, T. Notman, J. J. Polland, R. K. Richardson, J. T. Rossouw, G. Solomons, G. P. Stulley, I. Turnbull, H. W. Weisman, S. Wiederlight.

G. C. Laszlo, a graduate of a recognized foreign university, was also admitted a licentiate.

The Services

A Bar to the M.C. has been awarded to Capt. J. S. Lancaster, M.C., R.A.M.C., and the M.C. to Capt. (temp. Major) A. M. George and Capts. M. S. Chayen, G. Dison, and C. F. Young, R.A.M.C., in recognition of gallant and distinguished services in the Middle East.

The King has conferred the Efficiency Decoration of the Territorial Army on Lieut.-Col. (temp. Col.) R. E. B. Rees, M.C., Major (temp. Lieut.-Col.) C. L. Broomhead, and Major E. White, R.A.M.C.(T.A.).

Lieut.-Col. Eustace Trevor Neave Taylor, I.M.S., has been appointed C.I.E. for services in the Burma evacuation. The official citation in a *Supplement* to the *London Gazette* dated Jan. 29 reads as follows:

> "Lieut.-Col. Taylor was posted in Feb., 1942, to Kalewa on the refugee organization, where, by untiring efforts, he succeeded in checking a cholera epidemic among the refugees which might have brought work on the India-Burma road to a standstill and resulted in great loss of life. On the advanced refugee camps being withdrawn he became responsible for the medical arrangements in the Manipur area, at a time when reductions of staff and the state of exhaustion and disease in which the refugees were arriving made his task particularly difficult. Before leaving he had re-established the civil medical administration in Manipur. Throughout he displayed tireless energy, complete disregard of hardship, and outstanding organizing ability."

Lieut.-Col. David Kenneth Llewelyn Lindsay, I.M.S., and Major William McAdam, I.M.S., have been appointed O.B.E. (Civil Division) for bravery and distinguished services in the Burma evacuation. The official citations in a *Supplement* to the *London Gazette* dated Jan. 29 read as follows:

> "Lieut.-Col. Lindsay did magnificent work when Lashio was bombed and, by his personal influence and leadership, kept his hospital functioning at full strength and dealt with, in addition to bomb casualties, a large number of evacuees and many Chinese military patients. Although heavy fighting was going on just south of the Lashio–Hsipaw road and it was not clear how long the road would remain intact, he managed to get medical supplies to the Chinese military hospital at Hsipaw, which had been bombed and had lost all its stores. He then successfully evacuated the remainder of his patients from Lashio and stayed well in the rear, giving what medical help he could to the stream of refugees. After reaching Myitkyina he attempted to get medical supplies for the hospital Although well aware that the Japanese Forces were advancing rapidly along the Bhamo road, he went back 20 miles to the Kasu River, but was cut off and machine-gunned by the Japanese advanced guard He managed, however, to escape into China. His devotion to duty, cool fortitude, and courage during the Shan States retreat from the Japanese were of the highest order."
>
> "Major McAdam was in charge of the medical arrangements in the Chindwin area during the period of evacuation, and he contributed largely to the success with which disease along this route was kept at a minimum Although gravely handicapped by the state of the road and the lack of adequate transport, he was constantly on the move between Kalewa and Tamu, encouraging the medical staff at each of the camps, remedying, as far as he was able, deficiencies in equipment and medical stores, and generally helping the refugees on their way. He also assisted the military in the treatment and evacuation of casualties. His work was characterized by a calm devotion to duty in all emergencies."

CASUALTIES IN THE MEDICAL SERVICES

Prisoners of War.—Major S. C. Colbeck, I.M.S., Acting Major D. P. Dewe, I.M.S., Capt. A. K. Eastwood, R.A.M.C., Capt. J. E. Ennis, I.M.S., Temp Major G. A Graham, I.M.S., Acting Lieut.-Col. W. J. Leslie-Neal, I.M.S., Major S. G. Nardell, I.M.S., Lieut.-Col. L. G. Pearson, I.M.S., Capt. R. de Soldenhoff, I.M.S., Capt E. H. Wallace, I.M.S., Lieut.-Col. R. A. Warters, I.M.S., Capt E D. H. Williams, R.A.M.C.

Missing—Surg. Lieut. J. Robertson, R N

Medical Notes in Parliament

Tuberculosis Mortality

On Jan. 26 Mr. ERNEST BROWN informed Dr. Russell Thomas that the death rates per 1,000 of the total population from non-pulmonary tuberculosis in 1938 and 1941 in the following areas were:

	1938	1941 (Civilians only)		1938	1941 (Civilians only)
Glasgow	0.24	0.33	Radnor	0.10	0.18
Birmingham	0.08	0.11	Rutland	0.002	0.10
Liverpool	0.13	0.24	Pembroke	0.13	0.15
Manchester	0.14	0.19	Devon	0.10	0.12
Sheffield	0.08	0.11	Somerset	0.08	0.08
Leeds	0.12	0.10	Westmorland	0.08	0.14
Edinburgh	0.16	0.18	Bucks	0.08	0.09
Bristol	0.10	0.15	Dorset	0.10	0.07
Huntingdon	0.14	0.10	Bedford	0.10	0.11

The rates shown for 1941 must be regarded as being subject to varying and unknown degrees of distortion, owing to the fact that deaths occurring in institutions would have been assigned to the former areas of residence while the populations of such areas might have been materially diminished or augmented through evacuation or other war conditions.

The numbers of deaths of children under 15 years of age from non-pulmonary tuberculosis in 1938 and 1941 in the following areas were:

	1938	1941		1938	1941
Birmingham	36	50	Rutland	—	1
Liverpool	58	103	Pembroke	4	6
Manchester	49	55	Montgomery	4	1
Sheffield	22	34	Devon	14	23
Leeds	35	33	Wiltshire	11	25
Bristol	11	21	Somerset	8	21
Edinburgh	29	38	Westmorland	2	4
Glasgow	154	181	Bucks	13	19
Huntingdon	2	3	Dorset	14	11
Radnor	—	2	Bedford	16	20

On Jan. 28 Mr. DOUGLAS asked Mr. Brown to give the death rates from tuberculosis in the county of London for the years 1938 and 1941 respectively. Mr. BROWN said the special war-time conditions affecting population movements in London rendered any tuberculosis death rates for 1941 entirely misleading. Mr. DOUGLAS said the figures he asked for had been compiled by the county medical officer of health and published in the *British Medical Journal.* Dr. RUSSELL THOMAS asked if the figures published in the *British Medical Journal* did not show that the tuberculosis death rate in London had increased by 67% since the war. No answer was returned.

In reply to Mr. Thorne, Mr. BROWN said that in 1938 the number of deaths from non-pulmonary tuberculosis in the towns of Essex was 136, yielding a death rate of 0.079 per 1,000 population. For 1941 the available record related to civilians only, deaths and death rate being 163 and 0.126 respectively. Comparison of the two years on the basis of these figures was misleading, partly on account of selective recruitment for the Forces and partly because these towns, while depleted by evacuation, had been charged with the deaths of previous residents who died in institutions elsewhere.

Potato Flour

Mr. MABANE, replying to Major Thornton-Kemsley on Jan. 26, said that there were various methods of producing a satisfactory potato flour. His Department had, however, been anxious to avoid the construction of extensive new plant, and to find ways of utilizing existing plant, designed for other purposes but having the requisite capacity. Preliminary experiments with this object were begun at the outbreak of war. A fair measure of success had now been attained in large-scale trials. It would be appreciated, however, that the production of a suitable flour was only one of the factors to be considered in deciding whether or not to include potato flour in bread.

Maternity Provision by Local Authorities

On Jan. 26 Miss HORSBRUGH informed Mr. Thorne that according to the returns for 1941, which were the latest in the Ministry of Health, the hospitals with maternity provision carried on by local authorities, or with which the authorities had arrangements, and the nursing homes registered with them in the following districts were:

	Maternity Hospitals	Nursing Homes		Maternity Hospitals	Nursing Homes
Hull	1	7	Sheffield	4	15
Lincolnshire	14	10	Bradford	1	8
Manchester	3	19	Essex	18	81
Cheshire	12	70			

The Ministry of Health had also set up emergency maternity homes in the rural areas for use in wartime. Of these there were three in Cheshire, one in Lincolnshire, and one in Sussex There were also eight maternity homes or hospitals in Glasgow and 27 nursing homes.

Parliamentary Social Services Committee

Sir FRANCIS FREMANTLE has resigned the chairmanship of the Conservative Parliamentary Health and Housing Committee, which he has held for 21 years. Mr. S. Storey has been elected as his successor and the title of the committee has been changed to the Social Services Committee.

Shortage of Midwives

Mr. BEVIN, answering Sir Francis Fremantle on Jan. 28, said he was consulting Mr. Brown and the nursing and midwifery organizations to secure a better supply and distribution both of midwives and of nurses. Sir FRANCIS said the appeal made by Mr. Brown to nursing associations for midwives to remain as midwives had been useless. Many young nurses, after being trained as midwives, volunteered for general military service or went into munitions. Mr. BEVIN replied that Mr. Brown and he were attempting to organize that matter.

Expectant Mothers in Factories

Mr. HOGG asked on Jan. 28 whether the Minister of Health was satisfied with the steps taken to protect pregnant women engaged in employment in factories; and whether he was prepared to extend the present period in which employment was prohibited from one month after delivery to one of one month before and six weeks after delivery. Mr. BROWN replied that medical supervision under the Factory Acts was a matter for the Minister of Labour and National Service. Prohibition of employment was a matter for legislation. He had no authority to extend the period determined by Parliament. An extension of the prohibition could not be suggested without examination of the financial provision to be made for the women in question. Recommendations on this point were contained in the Beveridge report.

Diphtheria Immunization

Mr. LEACH, on Jan. 28, asked whether Mr. Brown knew that a boy aged 11 years developed a rare form of encephalitis after inoculation against diphtheria; that this boy was perfectly healthy until his first inoculation on July 7, 1942; whether the symptoms of encephalitis that caused his death some six weeks later began to develop after the second inoculation on August 11, 1942; how long he remained paralysed; and why this boy's death was not attributed to antidiphtheria inoculation. Mr. BROWN said he knew of the facts. There was a varying state of paralysis during the six weeks before the boy died. The coroner, with post-mortem medical evidence before him, did not find that the very rare form of encephalitis to which death was attributable had any association with inoculation against diphtheria.

Assistant Director of Hygiene at War Office

Replying on Jan. 28 to Dr. Morgan, Sir JAMES GRIGG said the adviser on venereology to the War Office held the full-time appointment of Assistant Director of Hygiene at the War Office with the rank of lieutenant-colonel. His duties were to advise on the prevention, diagnosis, and treatment of venereal diseases in the Army. His pay and allowances totalled about £1,300 a year. This officer was a member of the Regular Army Reserve of Officers. He reported for service on Sept. 1, 1939, under the conditions of his Reserve liability, and was appointed to his present post on Nov. 25, 1939. The appointment was not advertised. Officers of the R.A.M.C. were not allowed to set up in practice in competition with civil medical practitioners, but might see patients in a consultative capacity provided that did not interfere with their military duties.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* the downward trend of measles continues, with 496 fewer notifications than in the previous week. There was a large rise in the incidence of the other infectious diseases of childhood: scarlet fever up by 246, whooping-cough by 337, and diphtheria by 234. These figures represent rises on the totals of the preceding week of 12.5%, 22.4%, and 30.6% respectively. A further substantial rise of 210 cases, 17.5%, occurred in the incidence of acute pneumonia.

The North and Wales were the most affected areas. The biggest rises were: scarlet fever—Lancashire 81, Yorks West Riding 64; diphtheria—Yorks West Riding 91, Wales 45; whooping-cough—Wales 70, Lancashire 50, Staffordshire 39, Yorks West Riding 30; acute pneumonia—Lancashire 82, Yorks West Riding 47. The rises were fairly generally distributed, but there were some large local outbreaks—of diphtheria in Yorks West Riding, Batley M.B. 53, and Denbigh, Wrexham M.B. 24; and of whooping-cough in Montgomery, Llanfyllin R.D. 31.

The decline in the incidence of measles was mainly in the North. The largest of the decreases were those of Yorks West Riding 223, Lancashire 214, Staffordshire 159, Leicestershire 153, Durham 98, Derbyshire 88, Lincolnshire 84, Hampshire 82, Cheshire 67, Warwickshire 56. A rise in the incidence was recorded in London 120, Hertfordshire 68, Middlesex 51, Bedfordshire 47, and in Wales 89.

Dysentery increased in incidence from 14 to 31 cases in Lancashire (Blackpool C.B. 11, Blackburn R.D. 11), from 4 to 11 in Surrey (Chertsey U.D. 8), and in Essex from 15 to 19 (Colchester M.B. 13). A drop was recorded in London from 18 to 11. The four counties accounted for over 63% of the total cases in the country. There was a rise of 17 on the previous week's figure.

In *Scotland* the only changes of note were a fall of 78 in the notifications of scarlet fever and a rise of 40 in the incidence of acute primary pneumonia.

In *Eire* the large increase in the total of whooping-cough was due to delayed notifications: 75 cases occurring in November and December in a Dublin institution were included in this week's returns.

Influenza

A seasonal rise in the mortality from influenza occurs during the first months of the year, and following the expected trend the deaths from this disease have risen during the past few weeks. In the great towns 100 deaths were recorded during the week. It is nearly two years (March, 1941) since the mortality in a single week reached this level. Almost one-third more deaths have been reported in the first three weeks of this year than in the corresponding period of last year, but the number is only half of the total recorded in the same period of 1940 and 1939 and less than one-tenth of the 1937 level.

Returns for the Week Ending January 30

The notifications of infectious diseases in England and Wales during the week included the following: scarlet fever 2,272, whooping-cough 1,790, diphtheria 809, measles 12,601, acute pneumonia 1,528, cerebrospinal fever 113, dysentery 178, paratyphoid 33, typhoid 6. In the great towns 125 deaths were attributed to influenza.

No.3

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Jan. 23.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London) (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1943					1942 (Corresponding Week)

Medical News

A meeting of the Tuberculosis Association will be held at 26, Portland Place, W, on Friday, Feb 19, at 2.45 p.m., when a colour film on "The Treatment of Pneumonia" will be shown, and there will be a discussion on the report of the M.R.C Committee on Tuberculosis in Wartime.

A lecture entitled "Belief," arranged by the British Institute of Philosophy, will be given by Prof. H. H. Price, Wykeham Professor of Logic in the University of Oxford, at University Hall, 14, Gordon Square, London, W.C.1, on Feb. 19 at 5 p.m. Cards of admission may be obtained free of charge from the Director of Studies at University Hall.

A meeting of the Middlesex County Medical Society will be held at Hillingdon County Hospital, Uxbridge, on Saturday, Feb. 20, at 3.30 p.m. The programme is as follows: Mr. L. Fatti: "Extra-pulmonary Bronchial Cysts"; Dr. E. B. Jackson: "Schaumann-Boeck's Sarcoidosis," discussion to be introduced by Dr. C. Alan Birch and Dr. A. C. Counsell; Mr. H. Hanley: "Stress Incontinence in Women." Visitors, especially members of the American and Canadian Forces at present in this country, will be welcome.

A meeting of the Diagnosis Section of the Faculty of Radiologists will be held at 32, Welbeck Street, W., on Saturday, Feb. 20, at 10.30 a.m., when Dr. J. Blair Hartley and Major Eric Samuel will open discussions on "Stress Fractures" and "The Significance of Some Developmental Abnormalities of the Hip-joint" respectively.

A London Conference on Health, arranged by the London Trade Union and Labour Movement, will be held on Sunday, Feb. 21, at Conway Hall, Red Lion Square, London, W.C.1, from 2.30 to 7.30 p.m. At the first session Dr. T. O. Garland will speak on health in industry, and at the second Dr. Joan McMichael will open a discussion on health in the boroughs. The conference fee is 1s.

The Charter Centenary meeting of the Pharmaceutical Society of Great Britain will be held at 17, Bloomsbury Square, W.C., on Thursday, Feb. 18, at 7 p.m., when the president, Mr. W. Spencer Howells, will give an address.

A demonstration of postural and remedial exercises, including the showing of the R.A.F. film "Fighting Unarmed," has been arranged by kind permission of the Air Ministry, at the Seymour Hall, Seymour Place, Bryanston Square, London, W.1, on Wednesday, March 3, beginning at 6 p.m. All registered medical practitioners are cordially invited to attend. Admission is free by ticket, obtained on application to the Acting Secretary, Board of Registration of Medical Auxiliaries, B.M.A. House, Tavistock Square, London, W.C.1.

Tuberculosis officers of local authorities are to be asked to furnish reports on the condition of ex-soldiers who are in receipt of a disability award for pulmonary tuberculosis contracted during peace-time service, and who are at present periodically examined by a medical board. A Ministry of Health circular (No. 2757) states that it is hoped thus to obviate the need for regular attendance of these men at medical boards. The report, for which 5s. will be paid, will be made, in response to a request from the Army medical authorities, on Form 228 and should be returned as directed together with a claim on Army Form P.1922 for the fee.

The publication of several reports which have attracted wide attention (including a memorandum summarizing official policy on A.R.P., and an address by Prof. J. A. Ryle on "Hospitals and Air Raids"), the issue of Press announcements, and monthly committee meetings addressed by invited speakers were a few of the many activities during 1942 of the National A.R.P. Co-ordinating Committee. The committee has also stimulated local conferences on Civil Defence all over the country, and has carried out an investigation into the state of the "public knowledge of A.R.P." which, in the committee's view, is regrettably low.

Application is invited for Leverhulme Research Fellowships and grants in aid of research. They are intended for senior workers who are prevented by routine duties or pressure of other work from carrying out research. They are limited to British-born subjects normally resident in Great Britain. In exceptional circumstances the condition as to residence may be waived. The trustees will also consider applications from groups of workers engaged upon co-operative programmes of research, particularly from those engaged upon long-distance programmes or in institutions in which the normal facilities for research have been curtailed by the war. The duration of the awards will not normally extend over more than two years or less than three months, and the amount will depend on the nature of the research and the circumstances of the applicant. Forms of application may be had from the secretary, Dr. L. Haden Guest, M.P., Leverhulme Research Fellowships, Unilever House, Blackfriars, London, E.C.4. Applications must be received by March 1.
